The conservation of water for irrigation and power purposes stands on an entirely different footing in the northern and southern halves of the arid region. In the northern half, reservoirs can be placed in the channels of running streams and endure. The silting process is so slow that the cost of removing the sediment, if it ever became necessary, would not be prohibitive. This is shown by the fact that the natural lakes in the streams of this region have been there for unnumbered centuries without being filled or greatly reduced in area by silting. Yellowstone Lake in the channel of Yellowstone River, Jackson Lake in the channel of Snake River, Fremont and Wind River Lakes in the tributaries of Green River, Lake Tahoe in the channel of the Truckee River, and Klamath Lake in the channel of the Klamath River, are illustrations of conditions that make reservoirs a safe basis for both agriculture and power development in practically all the region north of Arizona and New Mexico.

* Berkeley, Cal.

Mr. Mead.

South of this region, there are no natural lakes in the channels of streams. The heat, the aridity, and the torrential character of the rainfall, are friends of erosion, and help to explain the high percentage of silt which these streams carry at certain seasons. To build storages in these channels, in the absence of some definite plan for insuring their permanence, ought not to continue. It is one of the matters which ought to be investigated, and one in which actual conditions in all existing reservoirs ought to be known and published, in order that this menace may be faced and, if possible, some plan worked out of averting the danger. Mr. Robinson has rendered a service to the whole country by publishing the facts.

Referring to some plan for desilting, the writer's attention has been called recently by L. C. Hill, M. Am. Soc. C. E., former Engineer of the U. S. Reclamation Service, who had much to do with the preparation and execution of the plans for the Elephant Butte Reservoir in the Rio Grande, to the fact that provision has been made for lengthening the life and usefulness of this reservoir in another way.

This provision is as follows: Instead of building a reservoir capable only of meeting the demands of the land it was to irrigate, the height of the dam was increased so as to give the reservoir a large excess capacity. This excess is so great that it is estimated it will be 60 years before the silt deposited will begin to reduce the storage capacity below the needs of the irrigated area. When that time arrives, the foundations and side-walls of the reservoir are of such a character that the height of the dam can be raised in successive stages so as to prolong the useful service of the reservoir for 300 years.

Such duration removes this reservoir from the list of temporary storages. Although it does not render it permanent, it does make it feasible financially to meet the expense of later storages higher up stream. The cost of the impounding dam of the Elephant Butte Reservoir would not be lost when the reservoir is silted up, as the dam will have great commercial value for the generation of power.

The writer has also learned that provision for a similar excess storage was made at the Roosevelt Dam and Reservoir. For many years silting will not encroach on the required volume of stored water and, as at Elephant Butte, it is possible to increase the thickness and height of the dam so as to prolong the useful life of this reservoir for centuries.

The writer did not have the Roosevelt Dam in mind in his reference to this subject, as it is in the higher reaches of a stream where erosion can be greatly retarded by preservation of the forests and vegetable growth on the water-shed of the reservoir. He was thinking

more of reservoirs built on the lower courses of streams, but makes this correction in order to avoid having his comments given a broader implication than was intended. Mr. Mead.

CLARENCE S. JARVIS,* ASSOC. M. AM. SOC. C. E.† (by letter).—Due to the deterring influence that will be exerted on meritorious irrigation projects now under way or about to be undertaken, as well as to the discouraging effect on the stockholders of existing systems pending a satisfactory solution for each enterprise where the silt problem is a serious menace, the subject dealt with in this paper has increased in immediate importance with the publishing of such conclusive data as are furnished by the author. The unfortunate condition that obtains concerning the relative aridity and the silt-bearing power of the streams, the greatest erosion usually taking place during the torrential run-off from the barren, parched slopes at the time of those occasional fitful downpours or "cloudbursts" indigenous to the Southwestern States, producing temporary rivers in the desert for a few hours, serves to increase the difficulty; for where it is most important to conserve the entire flood run-off and to maintain the maximum depth of storage to reduce evaporation, the introduction of vast quantities of sediment not only reduces the available storage capacity, but also increases the relative loss from evaporation, due to the increasing shallowness. Mr. Jarvis.

Factors that will enter into the solution or discussion of the problem, such as the relative quantities of water to be stored compared with the quantities passing the dam site, the gradient of the drainage and irrigation channels, the character of the sediment, the accessibility of the reservoir site for the delivery of construction materials and equipment, the limiting heights for the future storage, and the productivity of the land served with water under the various irrigation systems, will vary so widely as to require an independent solution for each case.

Apparent and Actual Capacities.—It is well established that the actual yield of a reservoir may be greatly in excess of the apparent capacity, due to the lateral extension of the stored water into the loose talus slopes so common to mountain valleys, or in some cases to the lateral infiltration into great depths of permeable soil. Inspection of the recently uncovered slopes of a receding reservoir will disclose numerous seeps and springs yielding the water from the underground reservoir, which represents the difference between the apparent and actual capacities. The writer has observed that, in the case of numerous glacial moraines on the borders of mountain lakes being converted into reservoirs, the excess storage capacity thus obtained in basins ranging from a few acres to more than a hundred acres amounted to from 5 to 20% of the apparent capacity. Also, the apparent capacity of a river valley filled with rock detritus and sediment is practically nothing; yet the wonderful success of submerged dams for the purpose of bringing

* San Francisco, Cal.

† Now M. Am. Soc. C. E.

Mr. Jarvis.

the underflow from such river deposits to the surface, proves that the safest and best reservoir sites, unaffected by the usual evaporation losses, are in the voids of sedimentary deposits. Perennial springs issuing from nearly horizontally stratified rock, or even from talus slopes on mountain sides, are occasionally successfully retained during the non-irrigation period, with a resultant increased flow when released.

While the percentages of voids in sedimentary deposits may vary from 40% for clean gravel and sand to 20% for fine silt, and in extreme cases the range may be outside of these limits, the actual yield for stream flow may amount to nearly 40% in the case of coarse material, and to practically nothing in the case of fine silt. In the latter case, the main losses of moisture are by surface evaporation, which is rendered continuous through capillary attraction until all of the excess or free moisture is removed from the sediment; while the seepage is so slight as to be lost by evaporation.

It is evident that a reservoir completely filled with clean coarse sand and gravel might retain from 30 to 40% of the original volume for effective storage, while the same basin filled with fine silt, or with coarse sediment mixed with enough fine silt to produce the maximum density, would retain possibly 15% of voids, but might yield less than 5% of the original volume of storage.

Removal of Sediment.—The ordinary methods of excavation with standard equipment, at several reservoir sites where the writer has been engaged as engineer, have resulted in an average cost varying from $1.00 to $0.10 per cubic yard of earth in large deposits. Using the lower unit price, the cost of removing 1 acre-ft. of sediment, approximately 1 600 cu. yd., would be $160, which could not be justified under current irrigation practice. The original cost per acre-foot of storage capacity in successful irrigation projects may run as high as $50, or as low as $2; with the rise in values of property in irrigation districts and with the reduction of maintenance expense on the canal systems, larger annual appropriations may be diverted each year for the recovery and maintenance of storage capacity, but a low unit cost for handling the material is imperative.

Apparently, the only method that may be used successfully for this purpose is some adaptation of hydraulic sluicing. The cost of pumping 1 acre-ft. of water against 100-ft. head, with power delivered at 1 cent per kw-hr., and an efficiency over-all of only 50% is slightly less than $2 for power. If the water carries a burden of fine sediment amounting to 15% by weight or 10% by volume, then the power charge for such pumping will amount to approximately $20 per acre-foot of dry sediment. It is not unusual for the plant and operation charge to equal the power charge; therefore, under such conditions, the cost per acre-foot of sediment removed would be $40. Fortunately, the sediment is seldom required to be elevated as much as 100 ft.; it is

usually sluiced out by way of the lowest channel, and the percentage of sediment carried need not be limited to 10% by volume if appropriate grades and equipment are used. Mr. Jarvis.

Consider now the type of reservoir ordinarily provided in the channel of a stream. For this case, assume an elongated site with a steep gradient in the channel, a high dam, and a stream run-off two or three times the original volume of the storage. Proper manipulation of the outlet gates, which should be of ample dimensions, together with judicious use of hydraulic pumps and jets from hydraulic giants mounted on a barge for use around the edges of the reservoir during the irrigation season and especially while the surface of the water is receding, reducing the larger deposits of silt and maintaining a turbid outflow, could be adjusted so as to keep pace with and correct the silting process. The alluvial silt thus distributed upon the irrigated land would be of immense value as a fertilizer; the canal system would have less percolation losses, and there would be less likelihood of the canal breaking than where clear water is used.

Under some conditions the plan suggested by Mr. W. W. Follett for combating the sedimentation menace at the Elephant Butte Reservoir might be advisable. This consisted of a conduit constructed in the bed of the reservoir and connecting the outlet with the Narrows about midway along the axis of the basin. This conduit would convey the sediment from the up-stream portion of the site to the outlet without allowing it to be deposited within the down-stream portion at any time. The up-stream area therefore would be an effective silt pocket for the main storage basin, and insure the delivery of turbid water for irrigation purposes. With such a conduit constructed through a reservoir site and provided with standpipe connections at intervals, the practical plan suggested by J. H. Quinton, M. Am. Soc. C. E., as Consulting Engineer for the Zuni Reservoir project, as related at the conclusion of the paper, the desilting of a reservoir site would be economically and effectively accomplished under ordinary conditions.

The type of reservoir that has no waste outflow lacks the advantage of the channel sluicing; but in other essentials the problem is similar to that previously described.

The preferable way to prevent excessive sedimentation is to reduce erosion; but this method certainly has its limitations. There is no doubt that the habits of some streams could be modified in this particular by planting suitable trees, willows, shrubs, and other vegetation, and protecting the banks against lateral erosion by barriers and deflecting structures wisely placed; and the value of the timber thus grown in the unforested regions would go a long way toward compensation for such improvements. The natural processes of erosion, however, will continue to some extent; and wherever reservoirs occupy the stream channel the burden of sediment must either be diverted, car-

Mr. Jarvis.

ried through by some natural or artificial sluicing, or else the reduction of storage capacity must be included in the reckoning.

Conclusions.—The writer cannot concur in the view expressed by Elwood Mead, M. Am. Soc. C. E., in his discussion, to the effect that the desert places should have remained barren until some feasible plan of desilting was worked out. If the future of the irrigation projects now most seriously beset with trouble from sediment should necessarily include abandonment, then the views so clearly expressed by Mr. Mead would meet with universal approval. Taking into account the influence of reservoirs upon the habits of a river, cutting off the peaks from floods and distributing some percentage of the flow that would otherwise be wasted to lands from which the underflow, when definitely established as the result of irrigation, will continue steadily for months or even years, one must conclude that the service from such reservoirs in establishing underground reservoirs of increasing capacity, compensates in part for the loss of capacity due to sedimentation. So important is the seepage flow as the result of irrigation that it is not uncommon for the owners of such projects to specify in the contracts of sale to homeseekers that the resulting seepage water may be collected by the distributing company and used as an integral part of the water supply for the project. The writer has observed that, where water was used copiously upon bench or plateau lands, the visible return flow became considerable after four or five years; and lands at lower elevation within the same project were being supplied in part from this source.

Reservoirs of elongated form along the main channel, through which large floods may flow freely for considerable periods, and which can be filled with the remaining flow after the stream has clarified in large measure, can be regarded as permanent and of practically constant capacity, irrespective of the quantity or character of the silt, as has been demonstrated in the Assuan Reservoir on the Nile. Inasmuch, however, as the regular and dependable habits of the Nile place this reservoir in a class by itself, the miniature reservoir projects that resemble the Assuan in essential features will require a somewhat modified treatment, and with varying degrees of success.

The main river channel through an elongated reservoir site represents a greater percentage of the original capacity than is realized at first consideration; and there can hardly be a well-founded claim that this portion of the reservoir will become a level mud flat. Some lateral erosion will occur naturally if the reservoir gates, of ample size, may be kept open for considerable periods, and this result would be obtained by the direct sluicing of the natural stream.

Departure from the simple process of direct sluicing through a reservoir basin immediately involves additional equipment or structures, such as conduits, pipe lines, pumping plants, barges, etc.; and

it would be necessary to make thorough study and skillful designs to avoid the uncertainties of experimentation. Reduced, however, to the simple requirement that the average silt content of the outflow shall be equal to the average burden of the inflow, the problem is capable of satisfactory solution in all except the extreme cases. The popular notion of the sediment carried by a stream is often based upon the observation of the maximum burden. The Rio Grande with an average silt content of 1.66%, and the Gila with an average of 1.3% during years of observation, have to receive and carry on the occasional contributions of liquid mud from their tributaries; and without the published data obtained by reliable observers, it is certain that a much higher silt content would be credited to these rivers by those who had casually observed the heavy floods. Mr. Jarvis.

The silt problem along the rivers of the Southwest is not more serious than the drainage problems that arise in irrigated districts: yet settlers and land owners and engineers cheerfully accept the challenge of these two lurking enemies of the irrigation project. Too often the first cost of the system so far overruns the estimate that there are no funds available, during the first years of operation, to give the needed attention to these matters; but it is fully realized that the accumulation of sediment in the one case, or the accumulation of seepage water in the lower lands and subsoil in the other case, increases year by year; and perhaps after ten or twenty years, or a longer period, when disaster is threatening the enterprise, pronounced steps have to be taken to correct the trouble and relieve an accumulation that should have been taken care of as a part of the maintenance of the project.

Mr. Robinson and Mr. Mead have rendered a distinct service to the Profession in presenting the data and views on this important topic.

GEORGE M. POST,* ESQ. (by letter).—The matter of silt deposition in the Zuni Reservoir has been the subject of a great deal of study, which its seriousness certainly warrants. Mr. Post.

When the construction of the dam had been completed, John B. Harper, M. Am. Soc. C. E., estimated, from such information as he had gathered during the years spent there, that the probable life of the reservoir would be thirty-five years. Mr. Robinson, who succeeded Mr. Harper as Engineer in charge of the project, has shown in his paper that the inflow of silt has been even more rapid than was predicted by Mr. Harper.

Several plans looking toward the disposal of this accumulated silt deposit have been proposed, none of which but has one or more insuperable objections. The writer has spent some time on this project and has made a more or less thorough study of the silt question. After having considered the disposal plans offered, he reached the conclusion

* Supt. of Constr., U. S. Indian Irrig. Service, Albuquerque, N. Mex.

Mr. Post. that the solution of the problem lay in the direction of prevention rather than disposal. In other words, to be, perforce, content with the present capacity of the reservoir and turn attention to the prevention, or at any rate the greatest feasible degree of diminution of the inflow of silt. When search was made for literature on the subject of prevention, it was found that there was almost none, although a great deal has been written about silt disposal.

The topography of the water-shed area of this reservoir is such that the average fall in the watercourses is steep and the resulting velocity is high. The soil, for the most part, is a very fine alluvium, in depth from 5 to 20 ft., most admirably adapted for rapid erosion even by slowly running waters. The majority of the rains on the water-shed are violent showers of short duration, which are also conducive to rapid erosion of the soil. The soil is never found to be moist more than a few inches below the surface. This is due to four causes: First, the annual rainfall is small, perhaps never exceeding 16 in.; second, the steepness of the slopes; third, for a number of years the water-shed area has been overgrazed by the hundreds of sheep and goats which the Indians have pastured there; and, fourth, a combination of the violent character of most of the rainfall and the fineness of the soil. This fourth reason probably requires a little explanation. It is well known that if a sack of flour is dropped into water, an impervious coat of paste will form around the outside and protect the interior for a long time from becoming wet. This same phenomenon occurs on this water-shed. Many times the writer has gone out after one of these storms, lasting from 1 to 3 hours, and has found this almost impervious coat of wet mud, only 2 to 3 in. deep, and perfectly dry soil underneath. This latter condition results in an extremely rapid run-off of the rain-waters, and sudden accumulation of large flows in the main water-courses which scour the stream beds at an extremely high rate.

It is obvious that if some means is adopted to retard the velocity of these rain-waters and hold them longer on the water-shed, the two results most desired would be accomplished. This is the statement of the possible solution, and it is very simple. Perhaps its practical application will be found to be considerably more complicated, and a much more thorough and careful examination of the ground must be made than opportunity as yet has offered. The plan, therefore, can be stated only in general terms.

Practically, the whole area of the water-shed is indented with numerous small gullies, which, running together, form larger ones; these, in turn, form still larger ones, and so on, until the main water-courses are reached. To check the velocity of the water in these gullies requires simple rock and brush structures varying in size and manner of building with the size and shape of the respective gullies. There is an abundance of cedar brush and rock immediately at hand,

and the cost of materials should be low. Care must be taken in the location and construction of these checks. The writer has seen numerous attempts at this sort of work fail by reason of improper location or construction or both. The water must not be allowed to run around the checks and form new gullies. One instance is recalled in which a check of this kind built in a gully to protect a road, simply diverted the water a few feet and now the new gully is larger and deeper than the former one. The checks must be built so as to prevent scouring out deep holes just below them. This difficulty is also of frequent occurrence. The spacing of the checks must also receive careful attention so that the velocity of the water will approach somewhere near that determined upon. This, of course, depends on the slope of the ground in each case. Mr. Post.

The work of construction should not be expensive. Over a water-shed of 659 sq. miles, a large number of these checks, of course, will be required and the total cost will amount to a fairly large figure. One point to be determined is "Will the results warrant the expense?" In the case in hand, the writer's opinion is that they will. Two main benefits will result from this plan. The first and most necessary is the prevention or material diminution of the inflow of silt to the reservoir, and the second, an increase of the absorption of rainfall by the soil. The secondary benefits derived from this last-named item will be increased vegetation and a very considerable increase in the flow of clear water down the stream.

As to whether the first result warrants the expense, the following considerations are the determining factors. The present maximum capacity of the reservoir is 8 290 acre-ft. During 1919 there was deposited in the reservoir a quantity of silt equivalent to 1 250 acre-ft.; should that rate of deposition continue, it will take seven years to fill the reservoir completely and destroy its usefulness.

It cannot be said offhand just what percentage of the erosion will be prevented by the plan proposed. It is, however, conservative to estimate that its quantity will be cut at least in half; and on that assumption, the life of the reservoir can be doubled. When it is considered that the cost of the construction of this dam has been upwards of $300 000 and that because of the construction of the dam, the Indians have been induced to cultivate more than 5 000 acres of land, the success of their crops being dependent almost entirely on the water stored in this reservoir, one would say that prolonging the life of the reservoir only seven years would fully warrant the total probable expense. It is certain that no argument would be needed to convince the Zuni Indians of that.

At the first opportunity, a careful and thorough examination of the water-shed will be made and a cost estimate prepared. It is probable that experience will dictate the construction of a number of different forms of these checks. The writer's idea at present is that most of

Mr. Post. them will be of simple rock and brush construction, built so as to withstand the flow that is likely to come to them, and nothing more.

It is more than probable that the full effects of this checking system will not be apparent for the first two or three years, because there will result a large increase in the absorption of the rainfall by the now dry and thirsty soil and this, as hinted previously, would cause benefits in at least three ways: First, there would be a sure increase in the quantity of vegetation on the water-shed area which itself would assist in further retarding the rainfall, the effect being accumulative; second, the slowly percolating water would eventually reach the reservoir clear instead of being so heavily laden with the destroying silt as is the present condition; third, an equalization of the flow of the stream would result, making more certain the water supply in times when a succession of two or three dry years occurs.

Mr. Robinson. H. F. ROBINSON,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer's paper contained records to the end of 1918. Another year has passed since then and the records for 1919 are now available. (See Tables 4, 5, and 6.)

Soundings were made in January, 1920, and it was found that the silt deposit had continued, and what was more regrettable, that the increase was greater than had been anticipated. It was found that 1 248 acre-ft. of silt had been deposited, while the average annual deposit for the period of 13½ years under consideration was only 557 acre-ft.

A greater quantity might have been expected, for the run-off was 46 473 acre-ft. of water as against an average for the period of 27 648 acre-ft., though observations had led to the conclusion that the average deposit did not depend on the amount of run-off, but was fairly constant. (See Table 4.)

The average silt content of the water during 1919 was 2.66%, or the least percentage recorded except that during 1918, which was the year of the greatest run-off.

The statement was made in the paper (page 875), that:

"It is generally believed that the quantity of silt carried by any stream is largely in proportion to the magnitude of the floods, but, according to the records at Zuni, little relation is found between the magnitude of the flow and the silt carried."

Since this statement was made, the writer has given the matter considerable thought and with the additional information secured during 1919, has decided that his former views were erroneous and that there is a relation between the run-off and the percentage of silt carried by the water. He believes that it may be stated as a general proposition that the percentage of silt carried by the water is in a certain

* Albuquerque, N. Mex.

Mr. Robinson.

TABLE 4.—SILT DEPOSIT IN THE ZUNI RESERVOIR.

All Capacities and Silt Deposits in Acre-Feet.

	Original, 1906.	June, 1910.	January, 1912.	January, 1914.	January, 1918.	January, 1919.	January, 1920.	Total period.

Lost capacity per year in percentage of original	.....	2.9	5.6	3.48	2.1	4.3	3.53	.....

Life of reservoir, Contour 990 = 21 years. Spillway at Contour 991. Capacity between Contours 990 and 991 = 507 acre-ft.
Life of reservoir, Contour 1 000 = 32.4 years.

Mr. Robinson.

inverse ratio to the magnitude of the run-off, within, as yet, undetermined bounds.

In any considerable water-shed it is well understood that any particular run-off may come from only a portion of the entire water-shed, and that the amount of erosion by this particular run-off will depend on the nature of the soil of that locality, so that two separate run-offs of about the same magnitude may carry a different quantity of silt, owing to the different geology and topography of the particular area affected. The varying character of the storm will also affect the rapidity of the run-off and, consequently, the amount of erosion; a long, steady precipitation would cause little erosion while a heavy downpour of short duration would bring down large quantities of silt.

In studying the periods of run-off between the times when the silt deposits have been determined, it has been found that there are six such periods, varying from 5 323 acre-ft. of water for a minimum to the largest one with 226 195 acre-ft., and carrying an average of from 12.5% for the smaller run-off to 0.58% for the greatest. These run-offs with the silt content expressed in percentages have been plotted on cross-section paper, and a tentative curve (Fig. 2) has been drawn, which fits the plotted points fairly well.

TABLE 5.—CAPACITIES, IN ACRE-FEET, OF THE ZUNI RESERVOIR AT VARIOUS TIMES, SHOWING ITS REDUCTION BY SILT DEPOSITS.

Contour.	1906.	June, 1910.	January, 1912.	January, 1914.	January, 1918.	January, 1919.	January, 1920.
940	0	.....	.....	.....	.....	.....	.....

975	3 758	2 256	1 190	407	53	12	.....
980	5 563	3 920	2 673	1 720	786	706	99.9
985	7 763	5 997	4 679	3 625	2 330	1 652	1 084.5
990	10 213	8 409	7 069	6 013	4 706	4 028	2 801.2
991	.....	.....	.....	.....	5 213	.....	3 287.4
995	12 887	11 062	9 721	8 664	7 336	6 660	5 410.8
1 000	15 811	13 969	12 632	11 562	10 218	9 540	8 292.1

With a greater number of points to plot along this curve, it is believed that a fairly typical and quite accurate curve might be produced, which would shed considerable light on this question, hitherto scarcely considered.

With the meager data at hand on which to work, these conclusions may be erroneous, but they are submitted for the consideration of the Engineering Profession with the hope that more light may be shed on the subject.

Mr. Robinson.

Total run-off, 1906 to 1919, inclusive, 373 252 acre-ft.

Mr. Robinson.

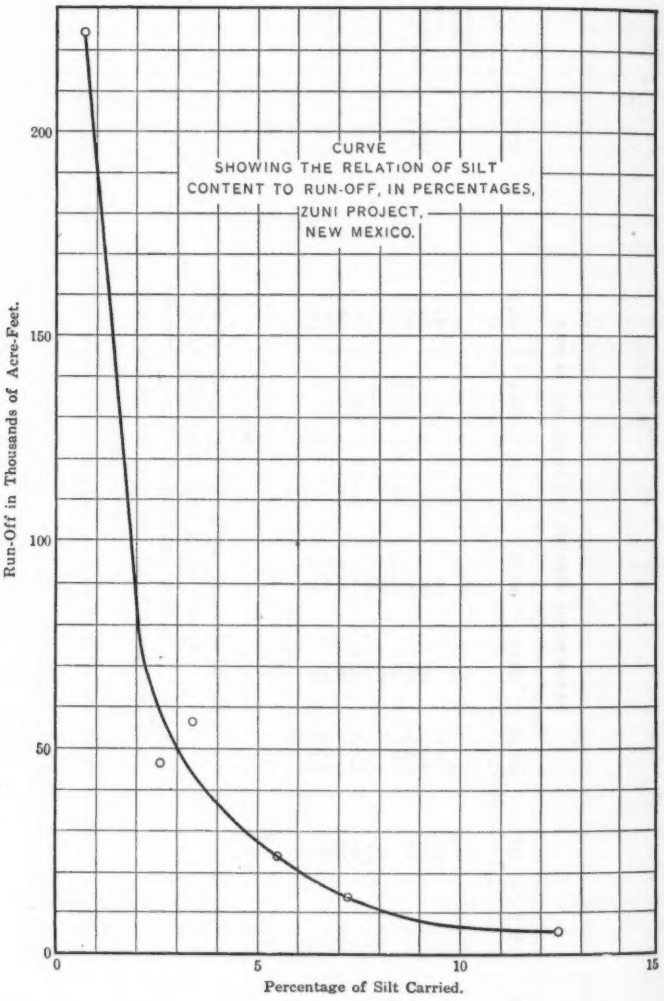

FIG. 2.

Mr. Robinson

The writer has read the discussion by Capt. Jarvis with great interest, and concurs with him in practically all his statements. The point made on the difference between the apparent and actual capacities of reservoirs in countries where the floors and sides of such reservoirs may be of gravel or other loose material and where comparatively large quantities of water may be stored in the interstices, which reappear, as the water recedes, in the form of seeps or springs, is a good one, and has been observed. Unfortunately, however, such a condition does not obtain at the Zuni Reservoir which is situated in a country formed almost entirely of sedimentary stones which on disintegration form a very fine sand or silt; gravel is unknown in that section. With such material, the actual and apparent capacity will coincide closely.

The discussion and suggestions for removal of the sediment are valuable and instructive, but for practice, in this particular case, engineers are again handicapped as there is no waste outflow at a low level, the only openings provided in construction being a number of 15-in. gate-valves in the outlet tower, placed at varying elevations, the lower ones of which have already been buried in the silt deposit.

The writer also concurs in the statement by Capt. Jarvis that the preferable way to prevent excessive sedimentation is to prevent erosion. The valuable discussion presented by Mr. Post, who has looked over the situation on the ground, covers this phase of the question in considerable detail, and the writer desires to offer his thanks for the suggestions presented. The discussions offered by both Capt. Jarvis and Mr. Post are constructive and doubly valuable from that standpoint.

Since the paper was published, some surveys have been made at Zuni, and it is found that it will be perfectly practicable to raise the dam and spillway another 10 ft., which will add perhaps 50% to the life of the reservoir. This will be carrying out to a small extent the suggestion of Mr. Mead that storage reservoirs of this kind be built with a much greater capacity than estimated for the needs of the project. In this case, however, the total life will still be small unless some practicable method of desilting is found.

Paper No. 1444

THE ACCURACY OF WATER-LEVEL RECORDERS AND INDICATORS OF THE FLOAT TYPE

By J. C. Stevens, M. Am. Soc. C. E.

Synopsis.

The continued advancement of hydraulic engineering is demanding a more extensive use of automatic devices for recording and indicating water levels.

Modern hydro-electric plants are not complete without indicators on the switchboard or devices that record the water levels in forebay, tail-race, net head on the turbines, or levels in some distant reservoir or supply canal. Every water supply investigation involves the recording of water levels in some manner, and no irrigation system can be operated successfully without obtaining and analyzing extensive records of water heights.

This paper is an inquiry into the degree of accuracy that may be expected from the use of automatic recorders and indicators of the float type. It shows that standard instruments now on the market are, in general, sufficiently accurate for most practical purposes, but that where an extraordinary degree of accuracy is required, certain corrections may be applied to the indicated or recorded heights, by which the true heights may be ascertained.

Sources of Error.

In Fig. 1 is shown the general principle on which all float-operated instruments depend. A float rises and falls with the water, which, by means of a line consisting of a cord, cable, tape, or chain, running over a pulley and counterpoised, operates the pen, pencil, indicating hands, or dials of the instrument. In rare cases, a solid rod or rack is used, but the effect is, in general, similar to the use of a counterpoised line.

With a counterpoised line there are three sources of error, which cause the indicated heights to deviate from the true heights:

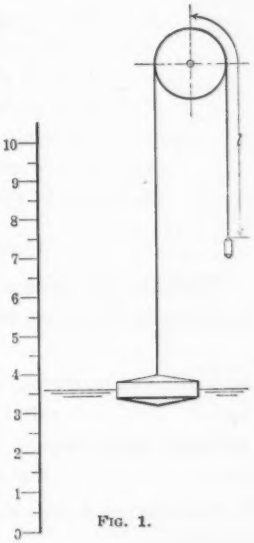

Fig. 1.

1. In operating the instrument there is always a certain amount of mechanical work which the float performs. Hence, the indicated heights on a rising stage differ from those on a falling stage by an amount proportioned to the force required to operate the device. This error will be called "float lag."

2. With every change of stage a portion of the line passes from one side of the float pulley to the other. Hence, the indicated heights deviate from the true heights by an amount depending on the range of stage and the unit weight of the line. This error will be called "line shift."

3. As the float rises the counterpoise and a portion of the line become submerged, unless provision against submergence is furnished. Hence, the indicated heights deviate from the true heights by an amount depending on the weight and specific gravity of the line and counterpoise. This error will be called "submergence of counterpoise."

In analyzing the effect of these three sources of error, the following notation, in foot and pound units, will be used:

Let W = weight of float.

c = weight of counterpoise.

u = weight per foot of the line.

L = total length of the line.
l = portion of the line on the counterpoise side of the pulley. (See Fig. 1.)
D = diameter of float.
A = area of float.
h = elevation of the liquid or gauge height.
h_1 = gauge height corresponding to submergency of counterpoise.
P = pull of the line on the float.
F = force required to operate the instrument.
w = weight per cubic foot of water or other liquid.
x = depth of flotation of the float with counterpoise in air.
x' = depth of flotation of float with counterpoise submerged.
r and f = subscripts for rising and falling stages, respectively.
s_c = specific gravity of the counterpoise.
s_l = specific gravity of the line.

Correction for Float Lag.

With the float resting on the water and the line attached thereto, as shown in Fig. 1, we have:

$$w\,A\,x = W - P \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

on a rising stage, the pull is,

$$P_r = c - F - u\,(L - 2\,l) \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

and, on a falling stage,

$$P_f = c + F - u\,(L - 2\,l) \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Substituting Equations (2) and (3) in Equation (1), we have for a rising stage:

$$x_r = \frac{W - c + F + u\,(L - 2\,l)}{w\,A} \quad \ldots\ldots\ldots\ldots\ldots (4)$$

and, for a falling stage,

$$x_f = \frac{W - c - F + u\,(L - 2\,l)}{w\,A} \quad \ldots\ldots\ldots\ldots\ldots (5)$$

Subtracting Equation (5) from Equation (4):

$$x_r - x_f = \frac{2\,F}{w\,A} = \frac{8\,F}{w\,\pi\,D^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Equation (6) gives the lag of the float between the rising and falling stages. It varies directly with the force required to operate

the instrument and inversely as the square of the diameter of the float. To make this error as small as possible, the friction and mechanical work of the instrument should be reduced to a minimum, and the float should be as large as practicable. This lag can never be eliminated entirely.

The force, F, consists of friction in bearings, gears, etc., of the pen or pencil on the paper, work of bending the line over the pulley, and, in the case of long-distance instruments, of making electrical contacts. It will vary with the condition of the instrument as regards oiling, freedom from dirt, etc., and may become inordinately large if the instrument is neglected. It is readily measured by balancing two weights equal to that of the counterpoise on a short piece of line over the pulley. Then, with the aid of a delicate spring balance or scales, the weight required to move the indicator is easily determined.

It has been proven experimentally that if the indicator is set to show the true height on a rising (falling) stage, then the true height on a falling (rising) stage at the same gauge height may be obtained by subtracting (adding) the quantity, $\frac{8\,F}{w\,\pi\,D^2}$, given in Equation (6). With a value of $F = 1$ oz., and an 8-in. float in water, this correction amounts to 0.006 ft.

In general practice, this is a negligible error, but the writer has seen several indicating gauges, where bottles were used for floats, sprocket chains for line, and the counterpoise was an iron index running in grooves over the face of a graduated staff, where this error amounted to 0.25 ft., or more.

It has been found experimentally that the friction factor increases with the weight of the counterpoise; in other words, with the weight on the pulley shaft.

To insure results within a reasonable limit of error, therefore, use a large substantial float, a small counterpoise, a light flexible line, and keep the instrument in good condition.

Correction for Line Shift.

The general equation for depth of flotation of the float is:

$$w\,A\,x = W - c \pm F + u\,(L - 2\,l) \ldots\ldots\ldots\ldots (7)$$

in which F is + for a rising and — for a falling stage. We may also write:

$$w\ A\ (x + \delta\ x) = W - c \pm F + u\ L - 2\ u\ (l + \delta\ l) \ldots\ldots (8)$$

whence,

$$\delta\ x = -\frac{2\ u}{w\ A}\ \delta\ l;$$

but $\delta\ l$ is the change in stage, that is,

$$\delta\ l = h_1 - h_0$$

whence,

$$\delta\ x = -\frac{2\ u}{w\ A}\ (h_1 - h_0) \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Equation (9) gives the correction for line shift. Obviously, the indicator may be set to show the true height at any gauge height, h_0. Then the correction to be applied is $-\frac{2\ u}{w\ A}\ H$, where H is the height above or below that point.

For a $\frac{1}{16}$-in., galvanized-iron sash cable, weighing 0.0065 lb. per ft., attached to an 8-in. float in water and a 10-ft. change in stage, this correction amounts to — 0.006 ft. In the case of the indicating gauges previously cited, however, it amounted to nearly 0.2 ft.

It is negative for both rising and falling stages above the origin of H, or the point at which the indicator is set to show the true height, and positive below.

Correction for Submergence of Counterpoise.

When the counterpoise and any portion of the line are submerged, the pull of the float is reduced and, consequently, the depth of its flotation is increased. The weight of any body submerged in water is reduced an amount $\frac{1}{s}$ of its weight in air, where s is its specific gravity. If submerged in any other liquid, s is to be replaced by its specific gravity with respect to that liquid.

When the counterpoise and a portion of the line become submerged, Equation (7) must be written:

$$w\ A\ x' = w \pm F - \left(l - \frac{1}{s_c}\right) c + \left(l - \frac{1}{s_l}\right) u\ (L - 2\ l) \ldots (10)$$

Subtracting this from Equation (7), we have,

$$x - x' = \frac{c}{s_c\ w\ A} - \frac{u\ (L - 2\ l)}{s_l\ w\ A}.$$

Now, at the point of submergence, $l = \frac{1}{2} L$. Consequently, the last term in Equation (10) disappears, and we have,

$$x - x' = \frac{c}{s_c w A} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

For a 1¼-lb., lead counterpoise and an 8-in. float in water, this correction amounts to 0.005 ft. This correction is always positive and tends to compensate for the error of "line shift."

Correction for Line Shift After Counterpoise is Submerged.

After submergence of the counterpoise, we may obtain a new value of the correction for line shift directly from Equation (9) by writing:

$$\delta x' = \frac{2\left(l - \frac{1}{s_1}\right) u}{w A} (h_2 - h_1) \quad \ldots\ldots\ldots\ldots\ldots (12)$$

For a $\frac{1}{16}$-in., galvanized-iron sash cord, attached to an 8-in. float in water, this correction amounts to 0.005 ft. for a 10-ft. change in stage, or 0.001 ft. less than for the counterpoise running in air.

Correction Diagrams.

The foregoing corrections are best applied in practice by preparing a correction diagram from which the combined corrections may be applied to the indicated heights to ascertain the true heights.

It is to be remembered that most instruments in good condition, if properly installed, will indicate or record the true height within a reasonable limit of error. It is only in cases where extraordinary accuracy is desired that these corrections need be applied. For example, in making tests of pumping plants where discharges are fluctuating and it is desired to secure continuous records of the head on a discharge measuring weir to within 0.001 ft.; or, again, if it is desired to measure the evaporation from a tank or reservoir, or the quantity of oil pumped into and withdrawn from a tank. In such cases, continuous records are required to a much greater degree of accuracy than in the ordinary practice of hydrometry.

Wherever such exigencies exist, they can be met by the use of ordinary recording instruments by applying the necessary corrections.

In order to prepare a correction diagram, it is necessary first to determine the constants of the instrument and its installation.

A prime requisite for all installations is a stilling chamber in which the float may move without being influenced by wave action, and where the line may be protected from wind.

Once installed, it is necessary to measure:

1. The diameter of the float;
2. The weight of the counterpoise and line;
3. The gauge height at which the counterpoise is submerged; and,
4. The force, in pounds, required to move the indicator.

To illustrate, a numerical example will be taken: The float has a diameter of 8 in. and weighs about 4 lb. The counterpoise is of lead, weighs 1¼ lb., is 0.2 ft. long, and is submerged at a gauge height of 5.0 ft. The line is $\frac{1}{16}$-in., galvanized-iron sash cord, weighing 0.0065

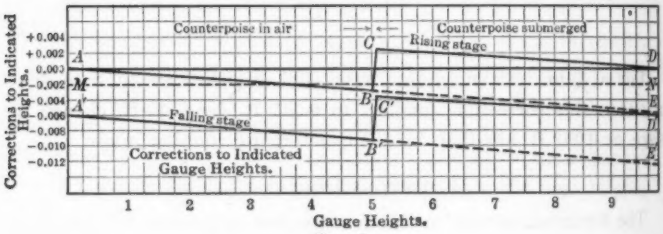

FIG. 2.

lb. per ft., and has a specific gravity of 6, since it has a hemp center. The force required to move the recorder pencil is 1 oz.

Substituting these values in the equations previously given, the following corrections are obtained:

1. For "float lag", Equation (6), the correction between a rising and falling stage is 0.006 ft.

2. Correction for "line shift" with counterpoise in air, Equation (9), is $-0.0006\ (h_1 - h_0)$ ft.

3. Correction for "line shift" with counterpoise submerged, Equation (12), is $-0.0005\ (h_2 - h_1)$ ft.

4. Correction for submergence of counterpoise, Equation (11), is $+0.005$ feet.

We have two correction lines—one for a rising stage and another exactly parallel at a distance of 0.006 ft. for the falling stage. These corrections are plotted in Fig. 2. The corrections for a rising stage are given by the line, *ABCD*, and those for the falling stage by

A' B' C' D', which is parallel thereto and 0.006 ft. below. The lines, *AB* and *A' B'*, have a slope of 0.0006 ft. per ft., and the lines, *CD* and *C' D'*, have a slope of 0.0005 ft. per ft. The lines, *BC* and *B' C'*, are the correction of 0.005 ft. for submergence of the counterpoise, which occurs in 0.1 ft. of gauge height.

If the counterpoise is run in a pipe from which the water is excluded, then the lines, *AE* and *A' E'*, represent corrections.

These lines are plotted on the assumptions that the pencil is set to record the true height at zero gauge height on a rising stage. In practice, the pencil must be set to record the true height at whatever height the water happens to be.

In order to obviate the necessity of constructing a new correction diagram for each setting, the correction lines may be drawn on a sheet of tracing paper. Then, by shifting this sheet up or down over the scale of gauge heights, the corrections for any setting are readily obtained. For example, set the pencil so that it indicates the true height on a rising stage at a gauge height of 3.5 ft. Then, shift the tracing paper until the correction line, *ABCD*, for a rising stage, intersects the gauge height line of 3.5 ft. at the origin of corrections. This is equivalent to moving the origin of corrections to the line, *MN*, in Fig. 2.

Any instrument may be set on the rising stage by pulling on the line on the side of the float until it is slack below the hand, then slowly releasing it.

It is seen from Fig. 2 that the maximum corrections are less when the counterpoise is allowed to submerge, than when run in a sealed pipe.

Instruments Performing Mechanical Work.

In some types of instruments a certain amount of mechanical work is done in addition to that of overcoming friction. For example, in long-distance recorders, electrical contacts are made at stated intervals of gauge height.

The pen remains stationary until the float has traveled the amount of the contact interval, then it suddenly follows the float that amount. The pen should nominally indicate the true height within an amount equal to the contact interval. However, if the pen is set to indicate the true height just after a contact on a rising stage, it will deviate from the true height just before a contact on the falling stage by an

amount equal to the contact interval plus the float lag due to friction alone.

In Fig. 3 are plotted the results of an actual test on a long-distance recorder. This instrument was one of the manufacturer's earlier types and had a nominal contact interval of 0.05 ft. (actually 0.0479). It was tested with a 10-in. float in a tank in which water and float heights were measured to 0.001 ft.

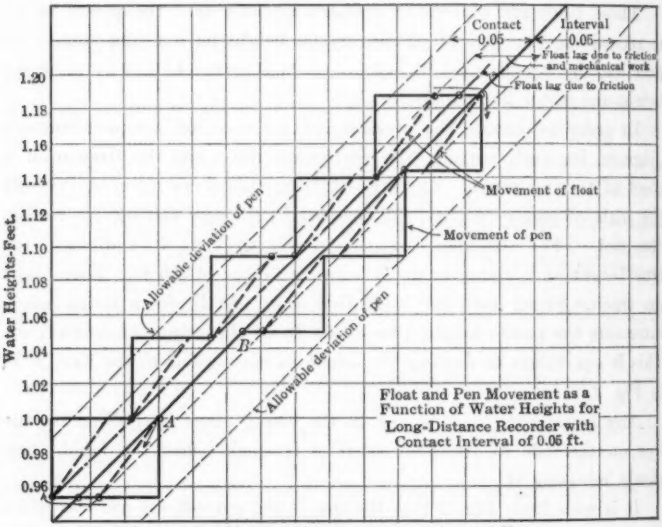

FIG. 3.

The pen was set just after a contact on a falling stage to indicate the true height, at the point *A*. The water was lowered, then raised, and lowered again to the point *B*. The float and pen movements are plotted as functions of water heights.

The float lag due to friction alone was 0.012 ft., and the lag due to friction and mechanical work was 0.036 ft. The pen, however, indicated the true height within the allowable deviation of 0.05 ft., except just before contact on the rising stage, when it exceeded the allowable deviation the amount of the friction lag 0.012 ft.

This error was inappreciable for this type of instrument, but could easily have been reduced by increasing the size of the float.

Similarly, in Fig. 4, are plotted the results of a test on a long-distance indicator built by the same manufacturers. This instrument had a contact interval of 0.01 ft., and the pen was to indicate the true height within that limit of error. During the test, the deviation was within that limit on the rising stage. On the falling stage, just the instant before contact, this limit was exceeded the amount of the friction lag 0.0007 ft. A 24-in. float was used. The instrument had a total range of 35 ft., but the maximum error due to line shift and submergence of counterpoise was less than 0.002 ft.

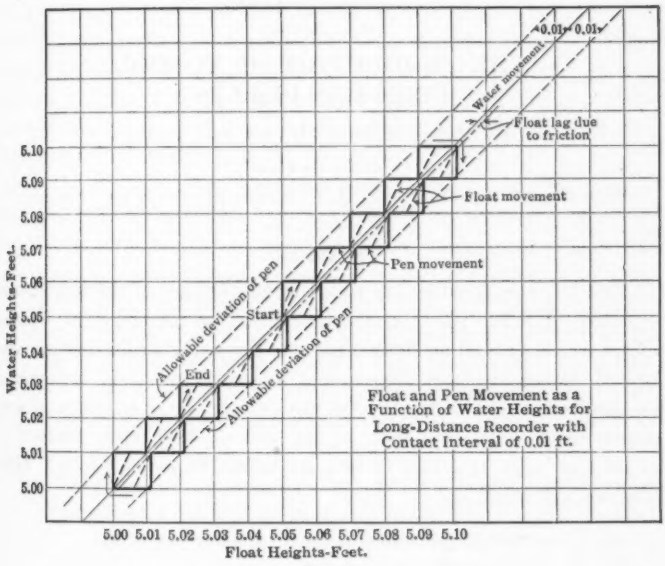

FIG. 4.

In conclusion, it is well to repeat that most recording and indicating instruments are well within the practicable limits of required accuracy, if they are kept in good condition. The best results are secured by using a large substantial float, a light flexible line, and as small a counterpoise as possible, allowing it to submerge at mid-range of gauge heights. Where greater accuracy is required, a correction diagram is readily prepared by which the true heights may be obtained from the recorded heights.

Paper No. 1445

THE PRODUCTION OF TOLUOL FROM GAS PLANTS

By Myron S. Falk, M. Am. Soc. C. E.

With Discussion by Messrs. A. C. Klein and Horace C. Porter.

Synopsis.

Toluol is the hydro-carbon which forms the base of the well-known explosive, T.N.T. In 1914, the production of toluol in the United States was estimated at 700 000 gal. for the year; during the war the United States Ordnance Department undertook measures to increase the production and, at the time of the signing of the armistice, it was conservatively estimated that, at the end of 1919, such production would have been at a rate of at least 32 000 000 gal. per year. This increase was obtained:

(*a*) By stripping gas manufactured in water-gas plants;
(*b*) By building coke oven plants;
(*c*) By cracking petroleum oils and solvent naphtha; and
(*d*) In various other ways yielding small quantities.

The development, with regard to stripping water gas, furnished interesting problems in connection with the standards of illuminating gas established by Public Service Commissions throughout the country and, for this reason, became involved in the National problem of the conservation of fuel. In New York City, the situation was further

complicated by State legislation which regulated not only the price of gas, but its quality.

This paper traces these complications, and brings forward for consideration the question, whether or not an enormous waste in fuel is still taking place, because of heat or light standards established when it was comparatively cheap.

At the beginning of the war the standard United States Army high explosive was Trinitrotoluol, more generally known as T.N.T., which is obtained by nitrating toluol, a colorless, oily liquid. Chemically, toluol is a hydrocarbon of definite composition, having the formula, $C_6H_5CH_3$, of the so-called benzene series. The specifications of the United States Ordnance Department require that its paraffin content shall not be more than 3% of the volume, and that it shall all distil between 109.4° and 111.4° cent. About 15 lb. of crude T.N.T., or 13½ lb. of refined T.N.T., can be produced from 1 gal. of toluol.

Prior to August, 1914, toluol was made in the United States to a limited extent, the production in that year being estimated at about 700 000 gal. It was used in chemical trades, as, for example, in the rubber industry and in the manufacture of saccharin, drugs, and dyes, but, for the most part, it was not separated from other oils with which it was manufactured. At that time, the principal source of toluol was from the by-product coke ovens, where it was obtained from the distillation of coal, in specially designed condensing apparatus; small quantities were also obtained from some of the gas companies from their gas-holders and drips.

Shortly after the beginning of the war, in 1914, both the British and French Governments desired great quantities of T.N.T., and, in consequence, many toluol and T.N.T. plants were placed under construction in the United States. By the spring of 1916, the capacity of the T.N.T. plants in this country had reached an output of about 5 000 000 lb. per month, and plants of less capacity were operating in Canada. Practically all the toluol needed for these plants was produced in the United States, and, in addition, some excess was produced and exported for nitration to British and French factories.

The urgent demand for toluol resulted in forcing its price to $7.00 per gal., in the spring of 1915. The price fluctuated between that and $4.00 per gal., until the spring of 1917, although trade journals have

recorded sales as high as $12.00 per gal. In April, 1917, the market price was $4.50 per gal.

It was apparent in May, 1917, when the requirements of the Ordnance Departments of the Army and Navy took definite shape, that there would be a most serious shortage in toluol. In June, a conference between these Departments, as well as representatives of England, France, Italy, and Russia, was held, and in July, 1917, the Council of National Defense appointed a board to investigate this situation. This Committee reported on July 27th, 1917, that the existing plants would not be able to meet the demand. A Sub-Committee on Coal Tar By-Products was formed and instructed to report as to methods to be followed to relieve the situation, and it was not until September 17th, 1917, that its report, with recommendations, appeared.

It is apparent, consequently, that, at the beginning of the war, the United States was not prepared to meet the situation with regard to its most important high explosive. Fortunately, the requirements of T.N.T. were considerably decreased in the fall of 1917 by the adoption by the Ordnance Department of amatol as the standard shell-filler for explosive shells. Amatol is a mixture of T.N.T. and Ammonium Nitrate, in proportions varying from 20% of T.N.T. and 80% of Ammonium Nitrate, to 50% of either, these mixtures being used at that time by the Allies as one of their standard high explosives.

The Gun Division of the Ordnance Department was charged with the responsibility of relieving the situation with regard to toluol, and Col. Jay E. Hoffer, then in charge, assisted by Col. (then Maj.) James H. Burns, requested permission from the War Industries Board, in September, 1917, to contract with gas companies for the construction and operation of toluol-recovery apparatus. There was formed, therefore, within the Gun Division, the Toluol Branch of the Explosives Section, which took complete charge of the constructive development of the toluol industry. Steps were taken immediately to investigate every possible source from which toluol could be derived, but, inasmuch as a definite recommendation had already been made to build apparatus in the works of gas companies to strip domestic gas of its light oil content, the first measures adopted were to negotiate contracts for the construction of such apparatus and to obtain the consent of the various gas companies and Public Service Commissions interested, so that this work could proceed.

These negotiations were most difficult, because stripping the gas decreased its candle-power. The question of the candle-power furnished by the gas companies to consumers had been for years a most delicate one, and, therefore, representations had first to be made to the Public Service Commissions requesting that the standard of candle-power be reduced. Amicable negotiations were concluded between the Ordnance Department and the Public Service Commissions in all cities in which it was desired to make such installations, except in the case of New York City, where the Public Service Commission laid down rules impossible for the gas company or the Ordnance Department to accept. The urgency of the situation in the case of New York City required drastic action, inasmuch as this city was expected to furnish a very large portion of the toluol. With the acquiescence of the gas companies it was determined, therefore, to proceed immediately to construct within the plants of the Consolidated Gas Company and the Brooklyn Union Gas Company thirteen stripping plants for the extraction of toluol, the Ordnance Department guaranteeing, for its part, to hold harmless the gas companies from any damages whatever caused either by the construction or operation of such plants, and the gas companies, on their part, agreeing to furnish the land free of charge and to operate the plants at absolute net cost, without any profit whatever.

Altogether, thirty-two gas-stripping plants were placed under construction in all parts of the country, from Boston, Mass., to Albany, N. Y., to Washington, D. C., to New Orleans, La., St. Louis, Mo., Denver, Colo., and Seattle, Wash., and contracts for the construction of all these plants were let as promptly as possible to three contractors, the work being divided between them as the judgment of the Toluol Branch deemed best under the circumstances.

It should not be thought, however, that the choice of location of these various plants was left to any haphazard guess. The Toluol Branch was very careful prior to awarding any contract to make tests of the gas that was being manufactured, to determine the suitability of its toluol content for nitration. Estimates of cost of construction and operation were gone into most carefully, the general rule laid down having been that no plant should be undertaken which would cost for construction more than the product obtained by multiplying its estimated yearly output, in gallons, by $2.00, and unless it could be operated at an expense not to exceed $1.50 per gal. of output.

Provision had also to be made for refining the crude toluol which was to be obtained from these gas plants, and for transporting both the crude and pure toluol, 250 tank cars having been ordered and purchased for this purpose alone. In addition, arrangements had to be made for the chemical control of the plants, to devise test methods for operation, and to instruct and drill the operators.

The gas which was stripped by the Ordnance Department, was usually carbureted water gas, manufactured by adding gas-oil vapors to a blue gas formed by the chemical interaction between steam and incandescent coke or hard coal. As a rule, from 3 to 4½ gal. of oil were added to each 1 000 cu. ft. of gas manufactured, the quantity of oil used being dependent on the illuminating quality and heat units required in the gas as finally sent out. In New York City, for example, the State laws required the standard for gas to be 22 c-p., and, for this purpose, generally, 4½ gal. of gas oil were required for each 1 000 ft. of gas. This gas contained approximately 650 B.t.u., or more, per cu. ft., and the gas-stripping apparatus through which it passed recovered as toluol about 2% of the gas oil used in the manufacture of the gas. In addition, however, to the toluol recovered, a considerable quantity of benzol and solvent naphtha was also recovered, the quantity of benzol being about one and one-half times that of the toluol and the quantity of solvent naphtha about one-half that of the toluol. These other by-products were also valuable for explosives, inasmuch as benzol was used as the base for picric acid, the favorite high explosive of the French, and solvent naphtha was in demand by the Navy for one of its high explosives—tri-nitro-xylol—although the manufacture of the latter by the Navy never reached quantity production. Large quantities of picric acid, however, were made in the United States for the French, particularly as a replacement to them of explosives loaned to this Government.

Toluol Recovery.

The gas, as manufactured by the gas companies, is passed through a tall tower filled with wooden grids through which an absorbent oil is circulated. The gas passes counter-current to this absorbent oil and loses its toluol, benzol, and xylol content, and is then distributed through the mains of the gas company to the consumers, without these light oils. The quantity of these light oils which can be absorbed, is

dependent both on the quantity of absorbent oil circulated through this tower, on its absorbing quality, and on the temperature and the velocity of the passing gases, so that wide variations of stripping can be obtained by manipulation. Later, the light oils are separated from the absorbent oil by the customary distillation processes using steam.

The gas which is then distributed through the mains, has lost a considerable portion of its candle-power, as well as some of its heat content. It is possible in some cases to add enough gas oil in the original manufacture of the gas so that, even after scrubbing, the gas will have the desired candle-power, but this method of retaining candle-power is most extravagant and wasteful, since oil is the most expensive ingredient used in the manufacture of gas; or, the gas may have its former lighting power restored by spraying back into the scrubbed gas other light oils, exclusive of toluol, but this, naturally, is also most extravagant, because these light oils have a distinct commercial value.

New York City.—In New York City, the Public Service Commission had made an official order insisting either that the full statutory 22 c-p. be furnished to the consumer, or that the gas company, not exceeding the period of the war, deliver gas containing 650 B.t.u. per cu. ft., with rebates whenever the gas dropped below this standard, and requiring, further, in the latter case, that each consumer using flat flame burners, on application, would be furnished with two incandescent mantle burners, and requiring, further, that the gas companies maintain a number of testing stations.

The gas companies refused to accept this permissive order of the Public Service Commission, and matters with regard to the operation of these plants made no progress, although their construction was actively pushed, and the 21st Street Plant of the Consolidated Gas Company, one of the largest of its plants, was ready for operation on April 14th, 1918.

Officials of the Ordnance Department had held frequent conferences with the Public Service Commission, but the Commission still held its ground that the consumers of New York City must be furnished either with gas of 22 c-p., or with gas fulfilling all the requirements of its order, and that, if necessary, either the Government would have to furnish additional gas oil to the companies, if the standard could be maintained by that method, or measures of operation would have to be adopted which would meet the order.

At this point there arose a further complication; the winter had been most severe, and the movement of all fuel supplies was extremely slow. It may even be remembered that the Fuel Administration during this time had ordered fuelless days, and it was absolutely out of the question to obtain for the gas companies more oil than they were using at that time. It was most difficult for them to obtain any oil at all, inasmuch as cargoes of it were frequently commandeered by the Army and Navy for direct military operations.

At a final conference held early in April, this situation was again explained by the Ordnance Department to the Public Service Commission, and the crying need for toluol was made clear. Under these circumstances, the Public Service Commission finally consented to permit the Ordnance Department to operate these gas-stripping plants as it deemed proper under the circumstances, it being suggested at that time that the gas to be sent to consumers should not fall below 18 c-p. and that careful records would be kept as to the complaints by consumers and as to additional quantities to be used by them.

By order of the Ordnance Department, the 21st Street Plant, therefore, was placed in operation on April 14th, 1918, followed in due course by the other plants. It was found that the consumers did not notice the difference in the quality of the gas, and experiments were carried out, therefore, at the Mutual Gas Company's plant, to determine whether further lowering would cause any complaints. The candle-power was dropped gradually at this plant from 18 c-p. to as low as 10 c-p., and yet no additional complaints were received from the consumers. When this situation was further explained to the Public Service Commission, the Commission acquiesced in permitting the representatives of the Ordnance Department to operate these plants at a standard lower than the 18 c-p. originally set, and, in consequence, a gradual decrease in candle-power output was effected at all plants until, at the time of the signing of the armistice, the average candle-power in New York City was approximately 16, and yet the consumers were apparently ignorant of the fact.

Careful records were also kept as to the loss in heat units resulting from the stripping of the gas, and it was curious that no exact ratio could be found between loss of candle-power and loss of heat units. It is probable that the average heat units in a cubic foot of gas which

averages 16 c-p., were in the neighborhood of 620 B.t.u.; in other words, the gas lost 27% of its illuminating power and less than 5% of its heating power.

Mention has been made of the serious shortage in the supply of oil during the spring and summer of 1918. The distribution of oil throughout the United States had been placed in the hands of the Fuel Administration, and one of its assistants conceived the idea that a tremendous quantity of oil could be saved for the country's commercial industries for war purposes if the gas companies throughout the country were prohibited from using their usual supply of gas oil. The Fuel Administration had taken a census of the total quantity of oil used by the gas companies for this purpose, and had estimated that the average heating value of the gas produced throughout the United States was about 600 B.t.u. per cu. ft. of gas, and that if a compulsory order were issued by the National Government ordering that no gas be furnished to consumers higher than 528 B.t.u. per cu. ft., that a possible saving would be made of about 0.7 gal. of oil per 1 000 cu. ft. of gas. This proposed action of the Fuel Administration was of the greatest importance to the Toluol Branch, which at that time had practically completed plants estimated to produce 5 000 000 gal. of toluol per year, and as the production of toluol was directly dependent on the quantity of gas used, this order would have resulted in a loss of production of 1 500 000 gal. of toluol per year from the Ordnance plants alone, and a loss of about 750 000 gal. from plants owned by private interests. The Ordnance Department, however, studied the problem, and obtained figures to show that the large savings in oil by such a reduction in standard were not as great as the Fuel Administrator believed, and efforts were made to impress the importance of non-interference with the production of toluol.

On April 23d, 1918, the Fuel Administration was preparing to issue an order forcing the gas companies to cut down their consumption of oil to 2¾ gal. per 1 000 cu. ft. of gas manufactured. It should be noted that this action of the Fuel Administration would naturally have the backing of all gas companies using gas oil in manufacture, as it would enable them to reduce their operating costs by a material amount and would possibly give them renewed hearings before Public Service Commissions for a re-opening of rate cases, which many of the companies,

because of increased costs, were then endeavoring to obtain. The Ordnance Department persuaded the Fuel Administrator not to issue this order (see Appendix I) without giving all the departments interested a chance to appear, and, on May 18th, 1918, a conference was held at the office of the National Committee on Gas and Electric Service. Many reports and statistics had been prepared by the gas industry to support the order of the Fuel Administration; in general, all gas company officials testified that the consumer received the same benefit from gas of low heating value as from gas of high heating value, while representatives of the Public Service Commissions and of the Bureau of Standards testified to the contrary. The Ordnance Department at no time took sides in the dispute as to the merits of this phase, as it recognized that such matters were not within its jurisdiction, but always based its arguments against issuing the order, because of its effect on the toluol programme, on two distinct reasons: (*a*), that the quantity of oil saved would not be great, inasmuch as the majority of gas plants would still require the same quantity of oil in order to produce toluol; and (*b*), in that case, the oil required in excess of that needed to furnish 528 B.t.u. gas, would have to be furnished to the gas companies by the Ordnance Department at an expense to it of many millions of dollars.

The Toluol Branch prepared statistics (Table 1) showing the production of toluol from gas plants, assuming the standards to remain unchanged and then to be established at 575, 550, and 528 B.t.u. per cu. ft. of gas, and also statistics (Table 2) showing the total quantity of gas oil used in the New England, Middle Atlantic, Middle West, Southern, and Pacific States, both in plants producing toluol and those not producing toluol.

On June 5th, 1918, a conference was held at the office of the Fuel Administration, at which representatives of the various State Public Service Commissions presented their views. On the following day, the Oil Administrator, and representatives of the Ordnance Department, discussed all the statistics that had been prepared, and, as a result of this conference, the Oil Administrator stated that he was convinced that the quantity of gas oil saved by issuing an order for a lower standard for gas would not warrant the order.

Consequently, the Ordnance Department considered the matter closed, but, apparently, interests connected with the gas industry were

Note.—Oil-gas process plants on the Pacific Coast are not included.

not satisfied. The Fuel Administration announced, about the end of June, that a Director of Gas Plants had been appointed, and the question of lowering the standard was immediately re-opened. On July 22d, 1918, the Director of Gas Plants called a meeting at his office, at which there were present representatives of the Fuel Administration, the Bureau of Standards, the War Trade Board, the National Committee on Gas and Electric Service, and the Ordnance Department. The Director of Gas Plants was very frank in announcing that it was his intention to have the Fuel Administration issue a notice ordering the standard of all artificial gas to be 528 B.t.u. per cu. ft. The Ordnance Department immediately took exception to the order as prepared (see Appendix II), basing its opposition on two broad claims: First, that the order as issued would save very little oil, and, second, that it would transfer millions of dollars from the Treasury of the United States to the gas companies. Because of these objections, the Director postponed issuing this order, and a further conference was called for August 28th, 1918, at which representatives of the gas companies, the Public Service Commissions, the Fuel Administration, the Bureau of Standards, War Industries Board, War Trade Board.

and Ordnance Department, were present. At this meeting only representatives of the gas companies were heard, and they were almost unanimous in stating that, in their opinion, the consumers would not feel the reduction in heat or light standards and that it was for the best interests of the country to reduce these standards. It seemed to the representatives of the Ordnance Department that the Director of Gas Plants had definitely determined to issue the order, and the matter was deemed so urgent that the Ordnance Department presented its case through the Chief of Ordnance to the Secretary of War.

In consequence, on September 7th, 1918, the Assistant Secretary of War addressed a letter (see Appendix III) to the Fuel Administrator citing the history of the case and requesting that the so-called 528 B.t.u. order be not issued. On receipt of this letter, the Fuel Administrator appointed a new committee consisting of the Director of Gas Plants, the Director of Natural Gas Plants, and a representative of the Bureau of Standards, to report as to the advisability of issuing this order. This Committee presented a divided report, the representative of the Bureau of Standards recommending that the order be not issued. The Committee finally agreed, however, as a compromise, that in place of issuing a mandatory order to the various gas companies throughout the country, a request (see Appendix IV) be made by the Fuel Administrator to local authorities throughout the country that they arrange with their service corporations to maintain as low a standard as could be considered consistent with efficient and good service, the object being to conserve the maximum quantity of fuel for more necessary purposes. The form of this request was satisfactory to the Ordnance Department, inasmuch as it left open to that Department a chance for appeal to local authorities should it be found that the toluol programme would be affected adversely.

The signing of the armistice, on November 11th, 1918, changed conditions again, and, shortly after that time, Dr. Harry A. Garfield issued the following notice to the press:

"U. S. Fuel Administration.

"Washington, D. C.

"B. T. U. Standard Not To Be Changed.

"United States Fuel Administrator, Harry A. Garfield, announced to-day that, under existing conditions, he did not feel warranted in

recommending to local boards the abandonment of existing gas standards as a fuel-saving measure.

"A special committee was appointed in connection with the Bureau of Standards to investigate the heat value of artificial gas, but since the creation of this committee, Mr. Garfield pointed out, the fuel situation has materially changed.

"Public Service corporations are asked to consider whether a reduction of British Thermal Unit Standards by companies under their jurisdiction, will actually save oil, with the recommendation that if a reduction in quality is ordered, there should be simultaneously a corresponding reduction in the price of gas. The statement says:

"'In July last the United States Fuel Administrator appointed a special committee in conjunction with the Bureau of Standards, to investigate the heat value of artificial gas with a view to recommending what change, if any, in the B.t.u. standard would save coal or oil. Since the creation of this committee, the fuel situation has materially changed. The production of bituminous coal has increased under the stimulus of the Administration to unheard of figures, and the situation is not as critical as last summer. Yet, it is probable that under zoning orders of the Fuel Administration, some gas plants throughout the country will not be able to receive their customary rate of coal, and this may necessitate a temporary reduction in gas standards.

"'At the cessation of hostilities the demand for oil and coal will be transferred to other channels and the pressing demand for immediate deliveries will be reduced to such an extent that the Fuel Administrator does not feel warranted in asking local boards to abandon existing standards.

"'While it is not within the province of the Fuel Administration to request thrift in general, Mr. Garfield desires to call attention to the fact that we are using our oil deposits perilously fast, and therefore Public Service Commissions should consider whether or not a reduction of B.t.u. standards by the companies under their jurisdiction will actually save oil. In the interest of the public, however, wherever a reduction in quality is ordered or approved, there should be simultaneously made a corresponding reduction in the price of gas.'"

Finally, it is most interesting to point out what the Ordnance Department did accomplish between May, 1917, and October, 1918. Table 3 shows that the production was more than doubled in that period; and it also shows to whom the supply was distributed. It should be remembered, however, that the work of increasing the supply was still under way at the time of the signing of the armistice; grant-

ing no unforeseen contingencies, the production would have reached 2 861 000 gal. per month by the middle of 1919.

APPENDIX I.

"UNITED STATES FUEL ADMINISTRATION
"OIL DIVISION

"WASHINGTON, D. C., MAY 17TH, 1918.

"ORDER.

"M. L. REQUA, *Director.*

"It appearing to the United States Fuel Administrator that it is essential to the National security and defense, and the successful prosecution of the war, that the greatest possible use be made of our supplies of petroleum,

"The United States Fuel Administration, acting under authority of an Executive Order of the President of the United States, dated 23 August, 1917, appointing said Administrator, and of subsequent Executive Orders, and, in furtherance of the purpose of said Order and of the Act of Congress therein referred to and approved August 10, 1917.

"Hereby orders and directs that until further or other order of the United States Fuel Administrator,

"The standard for artificial gas as manufactured for distribution, is hereby fixed at 528 British Thermal Units per cubic foot (Massachusetts standard), superseding all previous standards.

"The above order is to take effect immediately and to become operative with the least possible delay.

"Nevertheless, it is expressly understood that all gas companies, with toluol plants, shall use sufficient oil and shall conduct their operations in accordance with the requirements of the Ordnance Department, so as to obtain the maximum amount of toluol which their plants can produce; but the B.t.u.'s in the distributed gas, must not be reduced below the standard (of 528) fixed herein, without special license from the Ordnance Department.

"UNITED STATES FUEL ADMINISTRATOR."

APPENDIX II.

PROPOSED ORDER BY JAMES T. LYNN, DIRECTOR OF GAS PLANTS, JULY 22D, 1918.

"ORDER.

"1. It appearing to the United States Fuel Administrator that it is essential to the National Security and Defense, and the successful prosecution of the war, that the greatest possible use be made of our supplies of petroleum and coal.

"2. The United States Fuel Administrator, acting under authority of an Executive Order of the President of the United States, dated

23 of August, 1917, appointing said Administrator, and of subsequent Executive Orders, and in furtherance of the purpose of said Order and of the Act of Congress therein referred to and approved August 10, 1917.

"3. Hereby orders and directs until further or other orders of the United States Fuel Administrator:

"4. That in all plants in which artificial gas is produced for public consumption, and in which toluol or toluol-producing material is not recovered for the United States Government, or its contractors or agents, the use of gas oils and bituminous coal is hereby restricted to that amount necessary in each of said plants to produce gas having a gross heating value of five hundred and twenty-eight (528) British Thermal Units per cubic foot delivered to the consumer as hereinafter specified.

"5. That in artificial gas producing plants which now, or at any time hereafter, while this order is in force, recover toluol or toluol producing material for the United States Government, its contractors or agents, the use of gas oil is hereby permitted in excess of the amount specified in Clause 4 of this order, for the purpose of recovering such amounts of toluol or toluol-producing material, as is or shall be required in each case by the United States Government, its contractors or agents.

"6. That all illuminating-power standards of quality for artificial gas supplied for public consumption now in effect are hereby suspended.

"7. That heating value standards of quality in excess of five hundred and twenty-eight (528) British Thermal Units per cubic foot for artificial gas supplied for public consumption, are hereby suspended.

"8. That the requirement of heating value herein made shall be deemed to be fulfilled if the gas tested at any point within a radius of one mile from the manufacturing plant, shall have an average gross heating value of not less than five hundred and twenty-eight (528) British Thermal Units per cubic foot as determined from the monthly average of daily tests, and if the gross heating value of the gas so tested, in excess of this amount, shall be kept to a minimum as closely as the condition in each case shall permit.

"9. That this order shall be in effect on the fifteenth day of August, 1918, or within a period of thirty days thereafter, if the conditions in any artificial gas plant or the territory served by it require this time before the order goes into effect, but in no case shall the non-observance of this order be permitted beyond the 30-day period herein provided except by special permission of the Fuel Administrator.

"UNITED STATES FUEL ADMINISTRATOR."

APPENDIX III.

"SEPTEMBER 7, 1918.

"MY DEAR MR. GARFIELD:

"1. It is understood that the Fuel Administration is considering the issue of an order establishing throughout the country a fixed standard for artificial gas of 528 B.t.u. per cubic foot, as a measure of conserving oil and coal.

"2. I desire to bring to your attention the effect which such an order will have upon the production of toluol from gas scrubbing plants.

"3. As one means of meeting the serious shortage in the supply of toluol required for the Army Programme, special efforts have been made to recover the maximum amount of toluol from water gas plants. The Ordnance Department is spending over $7 000 000 for additional plant facilities of this character, and from the gas scrubbing plants so provided, plus those installed by private corporations, it is estimated that toluol will be recovered from 65% of the water gas produced in the country. The yield which the Ordnance Department has been counting on is predicated on the continuance of the present heat standards.

"4. If a 528 B.t.u. order goes into effect, it seems reasonable to assume that in order to maintain the required toluol production, the Ordnance Department will have to make arrangements to supply the oil at the gas stripping plants corresponding to the difference between the requirements to maintain the present standards and the proposed standard of 528 B.t.u.

"5. To this extent, it is believed that there will be no conservation of gas oil and the Ordnance Department estimates that they will be put to an extra and unexpected expense at a yearly rate of over $4 000 000 as applied to the gas stripping plants of Greater New York only, which figure may be increased to over $9 000 000 as applied to the whole country.

"6. If the above procedure is not followed, the loss of toluol production is estimated at 2 600 000 gal. per annum, which is sufficient for about 37 000 000 lb. of T.N.T.

"7. While it is extremely difficult to estimate the probable net conservation of gas oil which would result from the establishment of a 528 B.t.u. standard, it has been estimated that this figure for the entire country would probably not exceed 1 300 000 bbl. per annum as applied to the gas plants (including the Pacific Coast) not equipped to recover toluol.

"8. While it is understood that the continued use of gas oil at the stripping plants at the rate necessary to insure the full protection

of toluol expected, would not be prevented by the proposed order, the matter is so serious in its effect economically and otherwise on the Army Programme, that I have felt the problem should be presented to you in this way, realizing that it will receive careful consideration prior to final decision in regard to the issuance of such an order.

"Respectfully,

"(Sgd.) BENEDICT CROWELL,
"Acting Secretary of War."

APPENDIX IV.

"PROPOSED FORM OF REQUEST TO LOCAL AUTHORITIES REGARDING STANDARDS FOR HEATING VALUE OF GAS, BY THE FUEL ADMINISTRATOR.

"The United States Fuel Administration is undertaking to provide in every possible way for the conservation of fuel in order to minimize the shortage which is imminent under present war conditions and needs.

"The gas companies of the country are large users of oil, coal, and coke for making gas. After several months of investigation, it has been determined that a substantial reduction in the heating value of manufactured gas and the elimination of all illuminating power standards would, in many cases, result in a material saving of these fuels.

"In consequence of this the Fuel Administration has been contemplating the issuance of an order to all manufacturing gas companies in the country to reduce the heating value of gas delivered to consumers to 528 B.t.u. monthly average. Realizing, however, that such a reduction in the heating value of gas will, in some cases, reduce the cost of manufacture and also the quantity of service rendered and thus raise questions for local authorities to adjust, the Fuel Administration wishes to accomplish these desirable changes through the voluntary action of State Commissions or local authorities, rather than directly by its own order.

"You are, therefore, advised that it is the earnest wish of the United States Fuel Administration, as a measure essential to the national security and defense and the successful prosecution of the war, that you should, wherever conditions permit of the saving of fuel in this way, take such action as may be necessary to put into effect at the earliest possible date, not later than , a reduced war-time standard for manufactured gas as distributed to consumers, considering for this purpose a minimum of 528 B.t.u.

"The reason for suggesting 528 B.t.u. is that it is the lowest

that has thus far been tried out in practice in the United States. It is the minimum which has been in effect in Massachusetts since January 1st, 1918, and which has recently been adopted by the Connecticut Commission.

"It is the wish of the Fuel Administration that the gas companies should maintain as low a standard as is consistent with efficiency and good service, in order to conserve the maximum amount of fuel. Unless such a standard is put into general effect, there may not be enough fuel to supply the needs of gas companies generally throughout the country, and a large proportion, if not all of such companies, might have to be restricted in the use of fuel to an extent which would prevent them from maintaining existing standards.

"It is particularly requested that the regulatory bodies take such steps as will put this order into immediate effect, even in cases for which readjustments of the price for gas might appear proper to local authorities.

"Your compliance with these recommendations will be in the national interest and of great assistance and relief to the Fuel Administration and make the difficult task of rationing the fuel supply of gas companies unnecessary.

"The United States Fuel Administration does not wish under any circumstances, to restrict the fuel which toluol recovering gas companies require for the manufacture of gas and the recovery of toluol to the same extent as heretofore. Gas companies recovering toluol should, therefore, be permitted to operate in excess of this standard to whatever extent is necessary to produce toluol.

"Wherever the standards for gas quality are such as to restrict or prevent the satisfactory recovery of toluol, it is urged that they be modified when so requested by the War Department. Otherwise, this request as to a change of standard does not apply to any company producing toluol.

"As a further measure of conservation, the United States Fuel Administration urges local authorities to make every effort to obtain greater efficiency and economy in the domestic and industrial uses of gas. To secure a substantial improvement in efficiency and economy in the domestic and industrial uses of gas, it will be necessary to have the users of gas exercise care and intelligence in the choice of utensils and in the burning of gas. A large part of the gas made is used in cooking and frequently the net efficiency of such operations is not over twenty-five per cent.; by care it may be considerably increased. Gas companies can help the Administration by adjusting appliances properly and teaching their customers how to use gas economically. In the industries, also, care should be taken to use

gas but not to waste it. The use of mantle lights in place of open flame burners is to be encouraged, and pilot lamps should not be burned higher than necessary.

"The Fuel Administration will appreciate reply from the local authorities as to the action which is taken or contemplated on this request."

DISCUSSION

A. C. KLEIN,* ESQ. (by letter).—In addition to the experience in reducing the candle-power of New York City gas, the Ordnance Department, in its operation of the Government toluol plants, was confronted with similar problems in the Cities of Minneapolis, Minn., and Detroit, Mich. Mr. Klein.

In Detroit, the Gas Company was required to deliver gas of 20 c-p. and 600 B.t.u. Late in 1917, representatives of the Ordnance Department requested the authorities to reduce the candle-power, so as to permit the recovery of toluol at two plants, as contemplated. The City Council adopted a resolution reducing the standard to 12 c-p. and 600 B.t.u. during the operation of the toluol plant. The heating value standard was later reduced to 570 B.t.u., and although these standards were maintained until after the armistice, no record of any complaints was brought to the attention of the Ordnance Department, which was in constant touch with the plant operation, and particularly on the lookout for dissatisfied gas consumers.

The gas standard in Minneapolis, prior to the war, was 16 c-p. and 600 B.t.u. After negotiations for the operation of a toluol plant had been completed, the City Council was requested to reduce the standard to 10 c-p., so as to permit the operation of the plant without the use of additional gas oil. The Commission acceded to this request, and, later, further reduced the standard to 10 c-p. and 570 B.t.u., at which it remained until the toluol plant was shut down by the Ordnance Department. As in New York City and Detroit, no complaints of poor gas service had come to the attention of the Government inspectors.

To the casual reader of Mr. Falk's paper, it would appear that the Ordnance Department occupied an anomalous position in requesting a reduction in gas standards on the one hand, and in opposing a reduction on the other. There was, however, nothing inconsistent in its attitude. Its only concern was to obtain the maximum quantity of toluol, so that the T. N. T. plants might be kept operating at 100% capacity. Therefore, whenever a lower gas standard was necessary to permit toluol to be extracted, the Ordnance Department advocated a lower standard; when a lower standard would result in curtailing the toluol production (as would have been the case had the 528 B.t.u. order been put in force), the Ordnance Department opposed such a reduction.

This narrative of the action of the Ordnance Department in bringing about a material reduction in candle-power of the gas delivered in several of our largest cities, and its failure to affect adversely the interests of the gas consumers of those cities will be of great interest to the gas industry.

* Philadelphia, Pa.

Mr. Klein: For many years gas engineers have advocated that all candle-power standards be discarded, so that they might be enabled to take advantage of economical methods of gas manufacture and distribution, which they are unable to use when obliged to conform with high candle-power standards. Practically all regulatory bodies have recognized the soundness of this stand, and have substituted heating-value standards, setting them low enough to encourage the utilization of gas from by-product coke plants. However, our largest cities have been the ones to cling to the obsolete candle-power standard, claiming that a considerable number of gas users are dependent on open-flame lighting, and would suffer by a reduction in candle-power.

The experience in New York City, where the candle-power was dropped from 22 to 10, or 55%, without complaint from consumers, shows that there is no longer any good reason for retaining a candle-power standard. Standards of any kind are intended to serve the purpose of insuring to the purchaser a uniform quality of product, which quality should be as high as possible consistent with its price. In cases such as that of a public utility, where the price paid by the consumer is determined by representatives of the Commonwealth, the fair price necessarily bears a direct ratio to the cost of production, and public interest, therefore, demands that the standards should be such as to keep this cost of production as low as possible. The candle-power standard does not meet this test, and, therefore, it should be discarded.

In considering the question of gas standards, regulatory bodies should have broad enough vision to see the future sources of gas supply.

Our requirements for smokeless fuel are increasing at a very rapid rate, while the production of anthracite is increasing little or none. The shortage can be made up by the use of coke for domestic purposes. Coke is to-day a formidable competitor of anthracite, and the extension of its use will tend to keep anthracite prices down. The manufacture of coke in modern oven or retort plants yields a by-product gas which is in every way satisfactory for domestic cooking, heating, and lighting, although it cannot be manufactured to meet a high candle-power standard. To-day, more than a score of large cities, including St. Louis, Boston, Baltimore, Newark, Jersey City, Indianapolis, St. Paul, Hartford, Providence, Rochester, etc., are being supplied wholly or in part by such gas. None of the cities mentioned has a candle-power standard.

The authorities who are charged with the responsibility for protecting the interests of the public served by public utilities, and who have not yet recognized the wastefulness of the candle-power standard, should give full weight to the points brought out in Mr. Falk's paper, and should set standards of gas quality that will encourage the construction of large coal-gas plants. By so doing, they will be instrumental in creating a source of economical gas, as well as a source of smokeless fuel, which will act as a check upon the rapidly mounting prices of anthracite fuel.

Mr. Porter.

HORACE C. PORTER,* ESQ. (by letter).—The paper is particularly illuminating on the relationship of toluol production during the war to required standards for city gas. The author is to be congratulated on his clear and forceful presentation of the facts bearing on the treatment of this question by the War Department and the Fuel Administration during the war.

Attention may be called to an additional item, not mentioned by the author, in the increase of toluol production accomplished by the Ordnance Department. The coke ovens which at the beginning of the war produced 85% of the toluol supply, were assisted in obtaining coal of good quality, and in raising their yield of toluol per ton. An increase of more than 10% was thus obtained in their production, and four times that increase would have been possible with intensive effort and due co-operation on the part of all governmental agencies concerned.

The average production of toluol per ton of coal by coke-oven plants throughout the country was at the beginning of the war about 0.28 gal. During 1918, up to November 1st, ten plants (out of a total of thirty-five) averaged 0.44 gal. per ton of coal. The highest was 0.56 gal. With a coal mixture of reasonably high percentage of volatile matter (having regard for the necessary coke output) and with reasonably practical changes in operating conditions, the average yield of toluol from coke ovens throughout the country could have been increased to 0.40 gal. per ton, or by 40 per cent.

In December, 1917, the Fuel Administration was urgently requested by the Ordnance Department to take steps toward preventing the diversion of high-volatile coal from coke-oven plants, and to insure to these plants a full coal supply so as to maintain toluol and ammonia production. Belated steps were taken in this direction, but the results were not in evidence for several months.

The development of toluol supply from city gas plants was resorted to in the early days of the war because it would relieve the situation quickly. The old saying reminds us that "hindsight is better than foresight", but as we look back in the light of later experience it appears unquestionably true that the utilization of existing coke-oven capacity for toluol production at the highest possible efficiency and with fullest possible coal supply of highest percentage volatile matter would have yielded a large increase in toluol in a short time, and would have rendered unnecessary some of the more expensive of the Government installations at gas-works. Coke-oven plants under construction at the beginning of the war could also have been hurried to completion and their toluol production made available earlier.

Coke-oven plants and their benzol-toluol recovery equipment have a good post-war value, while city gas-stripping plants have little or

* West Conshohocken, Pa.

Mr. Porter.

none. Conservation is promoted by the former, and disturbed by the latter.

Had the Fuel Administration not failed to provide the coke ovens with the necessary coal for full toluol production in the early stages of the war, there would have been better ground for its subsequent plea for oil conservation at gas plants through the 528 B.t.u. standard and consequent toluol reduction.

Paper No. 1446

THE NATIONAL RAILROAD QUESTION OF TO-DAY.

AN ADDRESS BEFORE THE AMERICAN SOCIETY OF CIVIL ENGINEERS FEBRUARY 5TH, 1919.

BY FRANCIS LEE STUART, M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. T. KENNARD THOMSON, A. J. COUNTY, GEORGE W. KITTREDGE, CALVIN TOMKINS, AUGUSTUS SMITH, JOHN H. BERNHARD, G. J. RAY, HERBERT C. KEITH, CLEMENT C. WILLIAMS, C. A. MORSE, S. WHINERY, AND FRANCIS LEE STUART.

For an understanding of the Railroad Question of to-day it is necessary to review the facts which led up to Federal Control of the Railroads.

As one who had a hand in the development of several trunk line railroads with Ocean Terminals and has been otherwise connected with the Railroad subject in many ways, the important facts as I see them are:

For ten years before the war the clashing of State and Federal laws, the effect of the Laws under which the Interstate Commerce Committee worked or their interpretation of such laws gave indication that the railroads of the country, while in a high state of efficiency, were losing their attractiveness to investors, and many were losing their financial strength, so that the war found most of the railroads with small surplus in hand for meeting an emergency.

Early in our entrance into the war it became evident that the rush of material to the seaboard by all the unrelated efforts of the various departments of our Government and of the Allies, could not be handled by the shipping available, and that the physical and moral burden would fall on the railroads of the eastern section of the United States until

proper organization could be set up in the War Department to take care of the situation.

The eagerness with which every interest pressed the loading of cars, regardless of whether there was a prospect of prompt unloading of cars or not, and the inefficiency of the railroad embargoes began to congest the tracks, cars, and other facilities of the railroads, bringing with them their train of consequences, all of which tended to lessen the earning value of the properties; and, in addition, the buying power of the unit of value for which transportation service was paid rapidly began to depreciate, causing conditions which if prolonged would make a crash inevitable before the public could understand the real trouble and remedy it.

With our restrictive railroad policy, in order to save the transportation means of the country while it was still an efficient agent for winning the war, some Governmental aid had to be extended to tide over the situation. This aid finally took the shape of an Act of Congress, and the railroads were taken over under Federal control for the duration of the war and twenty-one months.

A Government agency equal in power to any other Government agency issued orders that cars were not to be loaded unless there was a definite arrangement for unloading; demurrage charges were increased and enforced; public opinion gave its moral support to orderly methods; the Government assumed the financial burden; and the railroads, as soon as the exceptional weather conditions of the first two months of Federal control permitted, with the same staff and the same equipment, began to function satisfactorily for war purposes.

A standard return was guaranteed for the use of the railroad plant; rates were raised so that the cost of transportation of the day should pay its way; wages were raised to meet the depreciating value of the dollar; and, in addition to those three vital essentials for handling the situation, the American practice of detouring and the placing of effective embargoes to avoid congestion was used on a large scale, and there was an insistence for a commercial business policy which provides a storage for unloading cars promptly to avoid the use of cars as a storage medium, all of which helped the transportation effort.

Under existing laws it was necessary for the railroads to be taken over for the winning of the war, and they were directed by the Director General of Railroads, for the President, with the single purpose of

making them efficient transportation agencies for winning such war, and the war is won.

The cost of a war must always be excessive, for obvious reasons, and there can be but little criticism of such actions as have been taken by this country, for when a republic is at war the resources of the nation should be utilized for the purpose of winning the war. Economic considerations, material and personal, must be disregarded when they interfere with that singleness of purpose.

It is best that the Governmental action of a republic at such a time should be as free as possible from criticism during the period of danger, and legitimate criticism can wait until time permits an analytical and impersonal investigation as a basis for criticism for the purpose of educating the republic in case of such a future emergency.

While on the subject of criticism, let me suggest that, although it may not be advisable to advocate that we draw a veil over all the acts of the war, yet we are all too prone to criticize, and let us in justice remember that the men who are responsible for getting our preparations under way and for the stupendous scale upon which we proposed to carry on the war, are the same kind of American Public School boys you and I are, and that we would probably not have done much better. And let us further console ourselves for our taxes with the thought that no one can tell what real effect the very scale of our effort had on the morale of the Germans, and how many thousands and tens of thousands of lives may have been saved thereby.

The war is won; the readjustment problems are serious, but, grave as they are, conditions are changed, and the happiness of the people and the due consideration of the economics of the country have become the paramount duty of the Government in solving these problems, and there is no reason why our re-adjustment problems should not be fully discussed.

Very fortunately for the country, an unusually able staff was selected for the United States Railroad Administration, but the fact remains that Federal Control of all the railroads as one road, with the best intentions and with bright minds giving their earnest thought to the Federal problems, while it has taught the country at large, and the owners, valuable lessons, which are worth all it has cost, has developed nothing of real material moment which it is desirable to perpetuate in peace times, or which has not been practiced under

private ownership, or cannot be more effectively practiced under private ownership.

The railroad question of to-day is what shall the Government do with the Railroad? Government ownership or Government control for five years, or a return of the railroads to private ownership as soon as possible?

Government Ownership.

Politics has no conscience, business morals, or responsibility, and the danger to our methods of government from the political control of the railroad employees, possible and probable, from Government Ownership, prohibits its serious consideration.

From an engineer's standpoint, this country is young, and its natural resources have hardly been scratched, and an experiment in Government Ownership would be extravagant, unfortunate, and undesirable on any basis, but primarily because it destroys the reward for initiative and sound judgment in the greatest field necessary for the proper development of our country and our national prosperity.

From the public's point of view, Government Ownership throttles competition, which is a necessary incentive for proper service to the people in every part of the country and every city in the land.

Control for Five Years.

Some of the things which were ordered with propriety during the war, which should be undone at once and not five years hence, are:

The Traffic Departments of the various railroads, which were dispersed, should in great part be re-assembled and re-habilitated at once. Such departments are as necessary in dealing with the public for the sale of transportation as the advertising and selling departments of any other business, and can be of great service to the public in many capacities.

An immediate abandonment as a national effort of an attempt at standardization of all manner of railroad necessities and methods. Such standardization, while it has a certain apparent first-cost economy when applied to quantity productions in the scheme of things in this country, tends to inefficiency, and should be a local question only in a limited locality. Our tools and methods are so crude that the national efforts should be to improve, not to standardize.

The horizontal raise in railroad wages of the entire country in one order which was necessary during the war is a pernicious destroyer of individual discipline, and atrophies the ambition of the men receiving such increase, and should be abolished in time of peace for responsible bargaining between employers and their own employees as soon as possible.

The discomfort of the public, some of which was necessary during the war, should give way to even better facilities than offered before the war, the direct tax of an increase of passenger rates should be reduced to a minimum, even if an indirect tax of increased freight rates is necessary to pay the bills. The movement of the people freely around and about our country should be encouraged as increasing happiness and social well being, and tending to a unity of spirit which is good for the body politic.

The discontinuance of regional consolidation, which was necessary for operation during the war, and an immediate return to a competitive basis in all matters pertaining to service to the public.

The terminal problem, which was made so acute by lack of ships and storage facilities, is largely one of changing our commercial methods, pooling facilities, and providing for the prompt unloading of cars. Belt railroads are needed and should be built in many places, but the matter is a local one peculiar to each community, and best handled as a financial policy of such community and not by the Federal Government.

We have great national efforts to make in world affairs, and the sooner we put the vim of an owner's interest back of the largest business interest in the country the better.

Return to Private Ownership as Soon as Enabling Legislation Can Be Passed.

This country is so young and undeveloped that the railroads should exist and be encouraged primarily for the development of our material welfare, and, for the good of all, the railroads should be returned to their owners as soon as possible so that their growth will naturally follow the normal business needs of the country tested by business standards and not directed into any pre-determined course which would be determined by a centralized Governmental agency.

Returning the roads to their owners under old conditions would bring financial disaster to insurance companies, savings banks, in fact, would mean financial chaos in the country; therefore, some legislation with certain Governmental controls is absolutely necessary.

The normal growth of our country requires that the railroads spend in the next five years at least four billion dollars for improvements, betterments, and normal growth of our transportation service, and a continuing and enlarging amount thereafter to meet our growing needs. While the Government finds it necessary to put out varying issues of Liberty Bonds, it seems best that they buy the securities of the Railroad as needed until the Public regains confidence enough to take the investment out of their hands. This will require a possible advance of from a billion and a half to two and a half billion dollars, for which the Railroads could be charged a high enough annual interest charge, over and above the cost of the money to the Government itself, to pay off the debt within twenty or twenty-five years.

It will take a stable continuing railroad financial policy to renew the confidence of the public in railroad securities, and it seems to me that the railroad interests of the country, which is the largest single interest, should write off all extraordinary war costs within a short generation and lesser business interests in less time—in fact, I think, to keep step with the age, the Government should find financial measures to write off and obliterate all or most of its national war costs within thirty to forty years or less.

The principle of a fixed financial policy and the control by the Government necessary to carry out such policy under all ordinary business cycles should be made a law by Congress. The control should be of an enabling nature and not more restrictive than is necessary, and might at the present time well consist of:

First.—A control of rates initiated by the carrier. The rate question is largely an artificial issue and little understood by the public. The shippers of the country are chiefly interested in rate relationships and the ultimate consumer in the amount of the rate, as he really pays the bill. We hear of the shippers through their lawyers, but the ultimate consumer is rarely heard, because his indirect tax due to the rate alone is so very small. There are possibilities in a more logical rate structure for settlement of most of the misunderstanding between

the public and the shipper, and between the shippers themselves, for which the railroads usually hold the bag. In connection with the control of rates, the Government should have an unbiased economic study made for a more logical application of rates than at present.

Second.—The wage question of the railroad employee, like other inflations of the war, will be settled sensibly by public opinion. It does not seem a proper Governmental function to settle wage scales, and it is for the best continuing interest of labor itself that such questions should be returned as soon as practicable to be settled between employers and employees. It is necessary, however, that the Government take cognizance of such matters in the control of rates.

Third.—A control of unproductive expenditures required by the public, and particularly as to the grade crossing elimination question which threatens to be of serious financial importance in the near future so that due cognizance may be taken of such expenditures.

Fourth.—A control of issue of securities for improvements and consolidations and of the necessary railroad accounts. Generally, the weak lines should be consolidated with the strong, and the large lines prevented from becoming so large that they eliminate competition from any section of the country.

Fifth.—A control in safety matters.

Sixth.—A recognition that for the continuing solvency of the properties the voice of the general public, whose welfare is at stake, and the voice of the owners of the properties, should be heard with that of the shippers and representatives of the employees.

In my opinion, the proper principles for legislation for a fixed financial policy should be based on an average railroad efficiently operated, receiving, as a minimum, a fair profit for the transportation it has to sell, and that fair profit must include:

1.—An adequate going return on the investment over the cost of proper service to the public;

2.—A return for such money as is borrowed for improvements required by the growth of the country, which will include the cost of the money plus an added equity to the corporation in compensation for extending their credit and brains as collateral for such money;

3.—The further right to build up such surplus as this class of business, wisely conducted, should have in reserve for emergency.

Nothing short of such a financial policy under private ownership will bring investors back to the support of the railroads and keep up the healthy growth of our country. Nothing short of such a financial policy, under private ownership, will give the people of our country a healthy sense of freedom and the right to demand competitive service for their happiness, comfort, and material benefit.

The matter of return of the railroads to private ownerships on a basis of such a financial policy can be applied at once without an absolute determination of results before the policy is adopted. For a willing trader, the securities and proper earnings on the investments of the average railroad with the many years of a repressive public policy putting increments of values into the properties, should not be difficult to determine within safe limits. On any given rate, some roads will fail and others will prosper, from many different causes, but the extremes can be regulated to meet the political feeling of the times by the beneficent use of an excess profit tax.

With the principles of a policy fixed, and controls whereby it may be made effective, the means for carrying out the purpose could be more flexible, and could consist of a number of commissions with some coordinating force, all safeguarded in certain cases by right of appeal to proper courts.

The entire matter is of such importance to the whole country that, if this session of Congress cannot settle the question, then an extra session should at once be called for this purpose. It seems to me, it is the simplest of our re-adjustment problems, and the one needing the most immediate attention, and the one most important for the immediate welfare of the country.

DISCUSSION

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—This is the most valuable paper the speaker has ever heard presented to this Society; its very brevity enhances its value.

The speaker is tempted to enter a lengthy discussion, but, for the sake of emphasis, will only mention two points, and those briefly.

Standard designs are all right in certain cases, that is, when the design is as nearly perfect as it can be made, and when used in the right place only. An old engineer once said: "A standard design is a stand-still design," and probably the most glaring offense in this line ever perpetrated on the public is the (can't sit still) design of the parlor car chair. The speaker has yet to find any one who was made to fit this uncomfortable seat.

As for Government ownership of railroads, the "proof of the pudding is in the eating thereof." It is known that the rates charged by the Government-owned railroads of Germany and elsewhere are much higher than in the United States, in spite of the shorter haul.

To come nearer home: Canada affords a very good comparison, for the Canadian Government spent $100 000 a mile to build the Transcontinental, and the Canadian Northern built an equally good road for $50 000 a mile.

Again: The Canadian Pacific Railroad spends $70 for interest and other charges to earn $100, and the Canadian Government spends from $200 to $220 for the same purpose.†

In other words, the Canadian Government spends twice as much to build and three times as much to operate as the privately owned railroads.

This is Government ownership as it was, is, and always will be.

Mr. County.

A. J. COUNTY,‡ ASSOC. AM. SOC. C. E.—The railroad situation has this gratifying feature: It demands thorough consideration, and, as the solution of the problem affects all citizens, the most experienced men should express their views freely. The speaker has listened with interest to many of the plans suggested to the Senate Committee in Washington, and congratulates Mr. Stuart on having "thrown into the ring" another plan which has so many sane features, and aims to preserve initiative and development in the transportation industry.

Should We Have Five More Years of Federal Control?—The situation impresses the speaker like this: The railroads have had Federal control and operation since January 1st, 1918, and, by Act of Congress, that control can continue for 21 months from the Declaration of Peace.

* New York City.

† Much valuable information about Canadian railroads may be found in a paper by W. F. Tye, M. Am. Soc. C. E., *Transactions*, Can. Soc. C. E., January–June, 1917.

‡ Philadelphia, Pa.

Mr. County.

The country is requested to endorse 5 years more of such control and operation. That means uncertainty, with consequent disruption of the experienced managements and organization, and it would be politically unwise and economically unsound for us to continue in peace the form of operation and control that the war period necessitated. There appears to be nothing to prevent the return of the properties to their experienced managements and officers to operate the same for the Government during the 21 months that will follow the Declaration of Peace. That allows sufficient time to adjust the situation, permits the Government to fund loans made to the railroads, give them a final settlement of compensation due for the use of their properties, including deferred maintenance of roadbed and equipment, caused by lack of men and materials in the war period, and for Congress to adopt a constructive railroad policy for the future.

What Future Policy Should be Adopted?—As to such future relations between the railroads, the Government, and the public, we must have an open mind. Happily for us, the world has had experience on all plans suggested, so that we are not left to much guesswork or assumption in reaching a proper conclusion. There must be determined which one of the three chief suggested policies should be adopted as best for the welfare of the country and its interests here and abroad to produce the best and cheapest transportation service, viz:

1. Government ownership and operation, and financing.
2. A regional guaranty plan by which the individual railroads are to be amalgamated and operated by about a dozen regional non-competitive companies, and the present railroad securities exchanged on some basis for Governmental guaranteed securities of the regional companies, the Government to provide future capital.
3. Private operation, under strict Government regulation, by the existing railroad companies, with competition in service and effort to serve the public; the ownership of said companies to continue to be vested in our citizens and in their savings, industrial, and other institutions, and the citizens to provide future additional capital for railroad expansion.

Government Ownership and Operation Opposed.—We can at the moment say definitely that Government ownership and operation will not meet with public approval, although its advocates are by no means asleep. The experience of the world is against it, as a sound political and economic method. A nation may favor it for military purposes, or for some special national emergency or purpose, just as our own country assisted the construction of the railroads to the Pacific Coast and in Alaska, and many of our States constructed railroads and other public transportation facilities in the past, but it is opposed to our

forms of progressive democratic institutions as a whole, and the activities and temperament of our citizens. Mr. County.

Should Regional Railroads and a Government Guaranty Plan be Adopted?—Therefore, we must consider the second suggestion, that of one dozen Federal regional companies, owning and operating under Governmental guaranties. The argument for regional companies under a guaranty generally proceeds along these lines: Just as the Federal Reserve System mobilized and protected the resources of the banks, so the resources of the railroads can be mobilized and their operations unified. Such a statement ignores the fundamental framework of the Federal Reserve Law.

Federal Reserve Regulation Compared with Railroad Regulation.—It produced an admirable system of financial responsibility and cooperative effort, but do not forget that individual banks were left untrammeled (so long as they observed honest and business-like banking methods) to make as much or as little money as they chose for their owners and to strengthen their reserves. That left private ownership and initiative of each bank free to act within the limits of the law and good management. Consequently, the banks have been the bulwark of the country in the hour of its financial stress. No argument is used that the interest rates which allow the little bank to exist make the big bank too rich at the expense of industry or the public. We realize that the strong bank is better able to serve the Nation, and that its profits are ultimately regulated by taxation and the stress of financial depressions or losses, the same as railroad rates and profits are regulated. Banking, like railroading, affects every citizen and every industry, yet we are proud of our strong banks—why not of our strong railroads? The railroads have regulation that corresponds to the Federal Reserve Board and the Federal Reserve Banks, in the Interstate Commerce Commission and the State Commissions. The serious difference lies in this fact: the country enacted constructive banking laws, but punitive railroad laws. The Federal Reserve Board and the Federal Reserve Banks are required to be constituted so that they cannot become purely political institutions. The Boards are required to be directed by representatives of banking, commerce, agricultural, or other industrial pursuits, in addition to representatives of the Government, and, in the case of the Federal Reserve Banks, stockholders are also represented; but, in the State and Federal Commissions regulating the railroads, no such constructive provision has been made.

Further, in the railroad regulation we already have Regions, with the States as boundaries, for the State Commissions; and, for the Interstate Commerce Commission, rates are not dealt with for the entire country, but in the various traffic regions; and we have railroad systems, competitive in service and with the necessity to earn profits.

Mr. County. Therefore, theoretically, we have enough machinery for railroad regulation now existing, largely similar to that of the banks; but we need the mandate of constructive railroad laws; we need the concentration of responsibility for railroad results and credit; and we need to add to our railroad regulatory bodies, now exclusively political, experienced men representing the activities of the country in industry, commerce, and agriculture, men who should be strong enough to enforce a National policy to insure the development of the transportation facilities and the credit of the railroads. First give the railroads constructive laws, and commissions, representing the country at large, responsible to enforce those laws.

Further, the suggestion of non-competitive regional guaranteed railroads, though it might produce some more co-operation, wipes out the element of competition in service and in endeavor to serve the public. We already have competitive regional systems, like the New York Central and the Pennsylvania Systems, that include hundreds of smaller companies, and more can be done when there is an earning basis to justify it. These regional systems preserve initiative and develop the country, but the regional railroad plan would unify all the railroads in that region, and would have no such incentive. There is nothing in the railroad situation to prevent further unification of the various railroad systems and their feeders, provided proper legislation is passed. Take the Pennsylvania Railroad: There are still about 140 active companies in that system, but they represent what were originally more than 600 companies. There has been a gradual evolution toward big systems which are competitive in service and in management. That is the healthy thing for the country, but our restrictive State and Federal laws stopped the process.

Should we Have a Government Guaranty?—As to the Government guaranty: This regional plan and Government guaranty is practically the French plan. Under a Government guaranty there would be no inducement to take further risks. Here is a serious element against which the commercial interests of our country must guard or we will have stagnation. The speaker can do no better than refer to the testimony of the English economist and lawyer, Mr. Acworth, before the Senate Committee, in May, 1917, amplified by quotations from the eminent French economist, M. Leroy-Beaulieu, which will be added to this discussion. We need not go so far for results of the guaranty plan. In various parts of our own continent the regional guaranty plan has been tried. The Federal Government has tried it for 1918 with regional operations and a guaranteed standard return. As the railroads earned a good excess over that return under private operation, it was felt that the Government, with all restrictive laws and commissions eliminated, would earn substantial profits over its guaranty. The results for the three years ending June 30th, 1917, justified the stand-

Mr. County.

ard compensation, which was equivalent to only about 5.2% on the road and equipment investment of the railroads. Just the same, whether we attribute it to war or other conditions in which economic results necessarily had to be overlooked, whether we say it is due to inefficiency or the great increase in the number of men and women employed, or the concentration of management from the local field to Washington, or the change from the trained managements, with private initiative and enterprise, to the regional plan, it produced a deficit, and we have not yet had the final figures. With all that, the speaker is willing to admit that the experiment justified the cost, considering the conditions confronting the country. The experience of Canada regarding the railroad guaranty will bear some careful reading. We know it is far from economic, and we know that the taxpayers will have to meet the huge loss. We have heard of the new era of "transportation for cost" on the Boston Rapid Transit lines, and the result will be an 8-cent or probably a 10-cent fare, or public taxation must meet the deficit. Indeed, we need not go outside of New York City to see what municipal ownership of the subways and the guaranty plan can produce. We know, fundamentally, that when a guaranty is given we take the first steps toward Government ownership, because the guarantor must assume the financial responsibility covered by its guaranty, and must also become finally responsible for the yearly capital improvements and financial budget, as well as for the final operating and maintenance results and service standards. Think of what it means in a country like ours, with changing political conditions and policies, and no party permanently responsible for the results.

Further, many of the advocates of the regional railroad guaranty plan require the practical financial reorganization of all the railroads in the country, the basis for which must be largely by capitalizing past net earnings or waiting for a final valuation, and, on the result, exchange existing bonds and stocks for those of the regional railroad companies. If any one can foresee the end of such a policy in a 10-year period, he is certainly optimistic. With present conditions, and with the load of war financing on the country, why add this additional load?

What Would Such a Government Guaranty Cost the Investor?—The railroad investor will first have to stand the results of such a financial reorganization and re-valuation of his property, and he must pay for the security of a Government guaranty. The general experience under the administration of such laws as the Railroad Valuation Law and the Federal Control Law is that they are slow and vexatious, and not by any means interpreted in a broad spirit, no matter what may have been the purpose of the framers. The investor, therefore, is bound to be sacrificed at the outset, and, in addition, under Federal guaranty

Mr. County. and regional non-competitive operation, he, as a taxpayer, will have to share in the higher expense of conducting railroad operations when they are freed from the competition that exists under private initiative and management. He is held out the hope of a minimum guaranty and a share in the future profits. What Governmental body will allow the rates to exist to earn profits over the minimum guaranty? What commercial organizations would insist that rates should be increased for that purpose? The disturbing feature is that our advocates of Government ownership, or of Government guaranty, probably feel that it is no longer possible, under our laws, or through our Courts, to retain private initiative and ownership and yet secure a just return to railroad owners on their investment, so that there can be no safety to the investor except by putting the burden on the country at large. If we have reached that state with regard to a railroad investment of $20 000 000 000 that affects the entire country, we are no longer safe, even under a Government guaranty, in holding any railroad securities. Under such a state of mind, where will our country stand in getting its share of the world's business, and carrying it at the lowest rates? There are other suggestions as to guaranty, but the plan generally urged requires regional companies to unify the railroads regionally as described, believing that such non-competitive unifications will realize savings, and they will be disappointed.

Railroad Executives' Plan—Private Ownership and Operation.—To guard against the two extremes of this situation, viz: Government ownership and operation, and non-competitive regional Government guaranty companies, the Association of Railway Executives produced a plan, published prior to any other, based on their experience and continued study of several years, recommending continued public ownership by our citizens and their institutions, with private initiative and management, under strict but responsible Governmental regulation, with the ability to co-operate with each other, free from restrictive laws. It avoids political management, operation, and financing. That system, notwithstanding all criticisms, has in the past produced railroads giving the best and cheapest transportation, as a whole, of any system in the world, has the lowest capitalized cost, and has paid the highest wages and the highest taxes in the world.

Exclusive National Regulation.—Their plan calls for the exclusive National regulation of rates, of interstate commerce instrumentalities, railroad security issues, and important capital improvements. It provides for the separation of the judicial from the administrative functions of the Interstate Commerce Commission.

Interstate Commerce Commission a Judicial Body.—It constitutes the Commission as the judicial body to pass upon the reasonableness and adequacy of rates, with power to prevent all discriminations in rates or service, and to supervise railroad accounting and valuation.

Regional Commissions.—The Commission is assisted by regional commissioners, convenient to the public in their several States, with power, subject to the Interstate Commerce Commission, to deal with regional transportation questions and rates in their territory, and can recommend betterments of the transportation service and facilities. Mr. County.

State Commissions.—The State Commissions would continue their regulation of intrastate questions and corporations, which have become such a large feature in our daily life, such as trolley companies, electric light, gas, water, heat, power, and sewerage companies, and other features.

Administrative Department of Transportation.—The plan further recommends the creation of a Department of Transportation under a cabinet officer called the "Secretary of Transportation," so as to concentrate the responsibility on the National Administration for adequate transportation service and facilities for the country; to protect the just interest of the owners and employees, as well as of the shippers and the traveling public; to deal with administrative questions, such as traffic distribution, joint use of terminals, proper car supply, and other railroad administrative and executive functions, so that promptness and the responsibility of the National Government would be continually back of the railroads. This officer, however, would not have the powers of the present Director General. He would not operate the railroads, nor appoint any of the officers or employees, and therefore no unavoidable hurtful political influence could be exercised by him, any more than has been exercised in connection with the appointment, removals, and other features of the State and Interstate Commissions. Let us not delude ourselves that politics will be absent from railroad questions in our democracy. Let us, therefore, make it the most responsible political influence on which the eye of the public is continually directed, instead of scattering the responsibility for railroad results over 48 States and Commissions. The speaker has little doubt that if the public preferred a small National Railroad Board headed by the Secretary of Transportation, but including representatives of business pursuits like commerce, industry, agriculture, finance, or railroading, to deal forcefully with railroad administrative questions, like the Federal Reserve Board, there could be no reasonable objection, but the Secretary of Transportation must be responsible to the President and the country.

The Railroad Executives' plan provides for the funding by the Government of the loans to the railroads during the period of Federal control.

Railroad Consolidation and Co-operation.—It also recommends further amendments of the restrictive Federal and State laws to enable the railroads to co-operate with each other to provide joint facilities for public convenience, and to enable the carriers to acquire feeding and

Mr. County.

connecting systems, and, to carry out more satisfactorily these beneficial forms, that Federal incorporation of the interstate carriers be permitted.

Rate Making.—The plan recommends that carriers have the power to initiate adequate rates, subject always to the approval of the Secretary of Transportation, and to final public review by the Interstate Commerce Commission as a judicial body, but rate initiation, suspension, and final disposition must be effected within 90 days, in lieu of the seemingly interminable periods in the past that so unsettled business and disrupted the railroads.

Statutory Rule to Fix Adequate Rates.—The final features of the Governmental control recommended by the Railroad Executives is a Federal law which shall include a statutory rule for making reasonable and adequate rates. If that power had been, or could have been, exercised in the past, there would have been no railroad problem, because the revenues would have been sufficient to offset rising costs and taxes, and attract the capital necessary to meet the railroad needs, and provide a basis to enable well established companies to sell stock as well as bonds on reasonable terms, and so prevented a great increase in the mortgage and fixed debt of the railroads. This rate-making rule has always been regarded as a difficult thing to lay down, because of changing conditions, and yet, in the decision of the Interstate Commerce Commission, they recognized that, when the situation arose in 1914 that the railroads earned only 5.36%, in the Eastern District, on their recorded investment in road and equipment provided for public use, the revenues were too low in the public interest. One can readily see that some minimum, like a return of 6 or 7%, on such property investment might be provided by statute, so that there would not be a repetition of restricted railroad credit, with its disastrous consequences and inadequate facilities for the commerce of a growing country. The speaker cannot see that such a minimum return would be objected to by the country at large, which has never desired weak or poorly maintained railroads, for that means business depression. This plan does not guarantee any return to any single railroad, but it will require, in substance, that the earnings of the railroads in the larger traffic regions of the country (such as the Official Classification Territory east of the Mississippi and north of the Potomac) should have an aggregate return which, as a whole, will always produce that minimum. This will still require each railroad to put forth its best efforts in operation and management to secure its share of the business and serve the public. The Railroad Executives' plan does not name any figure. Those the speaker has given are merely illustrations which, from his point of view, are essential to prevent future mistakes. It is quite usual for the State Commissions to fix rates of return permitted to public utilities. The water company serving the territory where the speaker lives is allowed to earn 7% in excess of operating expenses, taxes, and depre-

ciation. Whether or not the figure is imposed by statute, some protection is essential for railroad credit, because private ownership and initiative cannot continue unless returns are sufficient to pay operating expenses, taxes, and furnish a proper return on the investment so as to provide a proper basis for sound credit. No National railroad policy will be successful without embracing this rule of reason in rate making. That issue in railroad legislation and regulation can no longer be evaded. If it be conceded in legislation, and the railroads are liberated from the restrictive features of the anti-trust laws, and the State laws, what necessity is there for Government guaranties or Government ownership? Every guaranty or security issue of Governmental regional companies must weaken prices of other Government bonds, because the railroad guaranty concerns more than $19 000 000 000. Mr. County.

Wage Board.—The Railroad Executives' plan does not overlook the employees, nor the public necessity for uninterrupted transportation service. It provides for a Wage Regulatory Board, under the Secretary of Transportation, on which the public, the employee, and employers will be represented, so that the impairment of interruption of train movement, with appalling loss to the country, to the employees, and to the company, may be avoided, and lock-outs and strikes prevented.

Under such a far-reaching plan, the disturbance and economic waste heretofore caused by lack of a National railroad policy, and by divided responsibility, will be avoided, and there is no experimental feature about it. Like all other plans, it is, no doubt, susceptible of amendment, but it is hoped that our future National railroad policy will be adopted by Congress without Government ownership and operation, or Governmental guaranty of non-competitive regional companies, with consequent reorganization of the existing railroads, and with the resulting high transportation costs and paralysis caused by Governmental delays and restrictions, and inevitable stagnation to the future commercial progress of the country.

The following is the testimony of Mr. W. M. Acworth, of England, regarding Government relations to foreign countries, before the Joint Sub-Committee on Interstate and Foreign Commerce, before the Congress of the United States, in May, 1917:

The railway history of France stands by itself. Nowhere is the passion for logic and the love of symmetry which distinguish the French genius better exemplified than in the history of the French railway system. The ground plan of the policy which, broadly speaking, France has followed ever since, was laid down in a law passed as long ago as 1842. There were important developments after the world crisis in 1857, and again in 1878. And on January 1st, 1909, the Government, by taking over one of the six great systems, the Western, upset the symmetry of the original plan. But, with this exception, through-

Mr. County. out the whole history the original plan has stood firm. The whole country was divided up among six great companies, five of which radiate from Paris, and the sixth, the Midi, serves the extreme South and Southwest. The development of the railway network has been systematic from the outset; trunk lines first, then important branches, then the less important ones, and finally in recent years a considerable development of light secondary lines. Throughout, the State has guided, subsidized, and controlled. Each company has a monopoly of its own district. So far as possible, the points where the great systems meet are arranged not as in Holland, or formerly in Italy, at the great towns, but precisely at the points of least importance from a traffic standpoint. Where traffic is unavoidably competitive, as, for instance, from Paris to Central Switzerland, which can be reached either by the Eastern or by the Paris and Lyons Railway, arrangements are deliberately made to prevent competition. The Government controls all rates and fares charged and all services given, and the Government approves, not merely of pools, but of agreements by which shippers attempting to consign traffic by the route by which the railway companies have agreed the traffic shall not flow are deliberately penalized by higher rates. At a later stage of this paper more must be said of the work which the French railways have done, and reasons will be given to show that the French private companies have served their public at least as well as the Prussian State railways have served theirs. But it belongs here to deal with the history and the results of the nationalization of the Western Railway eight years ago.

For more than 30 years the French Government have owned and worked a system of lines in the Central West of France. This system was not inconsiderable in mileage (1 844 miles), but its district was purely agricultural and its traffic scant. It only reached Paris over the lines of the private companies, and, even when it served important towns such as Nantes and Bordeaux, it only served them by inferior routes. The financial results were very unsatisfactory—the operating ratio over a series of years ranged between 72 and 83%—but in some respects, as, for instance, admitting third-class passengers on all express trains, it gave to the public advantages which the private companies did not give.

Among the great companies, much the weakest financially was the Western. A large portion of its mileage was in Brittany, one of the poorest districts of the country. It did serve the town of Rouen and the very important port of Havre, but the canalization of the Seine diverted from the railway a large proportion of the valuable merchandise traffic between Havre and Paris. The French Government guarantees the dividend on the shares of all the French railway companies, and year after year the French Government had to find a considerable portion of the dividend to the Western shareholders.*

Further, large new capital expenditure was needed, especially to

* It should be noted that only 10% of the total French railway capital is in the form of shares; 90% is in the form of bonds which practically, though not formally, are guaranteed by the French Government. The dividend on the shares, therefore, though large in percentage—it ranges from 7% on the Western and the Eastern, and 10 or 11% on three of the other companies, to 13% on the Northern—is not very large in total amount. Broadly speaking, the companies other than the Western more or less earn their dividends in normal times without State help.

cope with the enormous passenger traffic of the company in the suburbs of Paris. How heavy that traffic is anybody who remembers the St. Lazare Station in Paris will know. The necessary capital could not be raised without Government approval; and Government approval, owing to strong parliamentary opposition, could not be obtained. Meanwhile, the service was going from bad to worse, and the equipment was on its last legs. Something had to be done. Once more the knot that could not be untied was cut; and, as from January 1st, 1909, the Government exercised its rights under the concession, and took over the railway, continuing to pay the guaranteed dividend to the shareholders in the form of an annuity running until the termination of the concession. Mr. County.

The political history of the transfer is distinctly interesting. The employees on the railway itself were unanimously in its favor; and, as subsequent experience proves, with good reason; and the whole strength of the Socialist Party and of socialist sentiment was thrown on the same side. A majority was secured for the bill in both houses, though a large majority of the representatives of the districts served by the railway voted against it. The bill passed the Chamber in December, 1906; but it was hung up in the Senate for 18 months, until June, 1908, and finally only passed by a majority of 3 votes, after M. Clemenceau, who was Prime Minister at the time, had given it to be understood that unless the bill was passed he would resign; and, much as the majority of the Senate disliked nationalization, at the moment they disliked the resignation of M. Clemenceau even more. It may further be added that, according to the French custom, the opinion of all the chambers of commerce in the country, which are statutory bodies, was invited on the measure, and that not one single town of more than third-rate importance reported in its favor.

Experience of State Operation in France.—Here in broad outline is the story of the result of the transfer.* In the 5 years, 1904-08, before the transfer, the gross receipts rose steadily from $37 084 000 to $42 145 000. In the 5 subsequent years, 1909-13 (the war upset entirely the figures for 1914), the gross receipts rose from $42 333 000 to $48 701 000, a slightly greater rate of increase. In the 5 years before the transfer, the operating expenses rose from $20 796 000 to $28 388 000, this last figure being unduly inflated by the fact that, from the date the chamber voted the acquisition of the railway, the staff became entirely demoralized. The first year after the acquisition the operating expenses were $30 304 000. The next year they were $34 921 000, and the year after, $39 454 000. In 1912 they had reached $41 800 000, and for 1913 they fell back to $41 478 000. In other words, to earn a net revenue increased by 31% the operating expenses increased by 100 per cent. The net revenue was never below $13 757 000 in the worst year of company rule. It fell to $5 352 000 after the Government had been in

* The figures given are from official sources. The story is mainly taken from an article by Pierre Leroy-Beaulieu, himself a Deputy, in "The State in Relation to Railways" (P. S. King and Company, London, 1912). See also Colson in "Revue Politique et Parlementaire" for November, 1910; December, 1911; May, 1913; and May, 1914. The railway newspapers all over the world were full of the story in 1909 and subsequent years. M. Colson, an engineer by training, was formerly head of the Railway Department of the Ministry of Public Works, and is now President of the Section of the Council of State (a body partly executive and partly judicial), which deals with all questions concerning transport by rail, or road, or water. His book, 'Transports et Tarifs," is a recognized classic on its subject.

Mr. County. possession 4 years. The operating ratio, which had risen from 56.4 to 67.8 under the company, was for the next 5 years as follows: 72.7, 79.9, 87, 89.4, and 85.2. It is fair here to make a qualification. The operating ratio had gone up on all the French railways between the two periods. It averaged 50.3 for the other five great companies for 1905 and 1906, and 58.4 for 1912 and 1913; but a rise from 50.3 to 58.4 is one thing; a rise from 56.4 to 89.4 is quite another.

A main argument used in Parliament in favor of transfer from the company to the State was that the company never did, and never could, earn its guaranteed dividend in full, still less the extra dividend which it would be entitled to if earned; that the company was accordingly a mere caretaker, and not interested in financial results, and did not operate, and could not be expected to operate, with economy. The State, on the other hand, would have a direct interest in operating economically. That was the argument. Here are the facts: During the last 10 years of company management, the State had to pay an average of $2 894 280 a year to meet its liability under the guaranty to make up the deficiency in net operating income. During the first 3 years after the transfer, the sums it had to find, under the same head, were $6 753 320, $8 875 792, and $14 934 484, respectively. For 1913, the figure was $14 752 237.

Nor do these deplorable financial results tell the whole story. The service to the public was absolutely demoralized. There were several very serious, and numerous smaller, accidents, and the staff and the public got so frightened that the express trains on the main line, already the slowest in France, were decelerated down to a timing that had been abandoned as inadequate in 1896. In addition, a number of trains were suppressed altogether. Punctuality went to the winds. Commuters on the system in the suburbs of Paris were compelled by their employers to live elsewhere because of the unpunctuality of their arrival at their work. As for the service in general, one figure will suffice. Compensation for accidents, loss and damage, averaged some $400 000 or $500 000 a year in the last days of the company. In 1911 the figure was $2 045 291. The Minister of Public Works himself publicly criticised the State administration as "a frightful fraud." And the Senate passed unanimously a resolution beginning: "The deplorable situation of the State system, the insecurity and irregularity of its workings * * *."

M. Leroy-Beaulieu gives the reasons for the "deplorable situation" as follows:

"In the first place, it is the abuse of formalism and red tape, with all the delays which follow and which are directly in conflict with commercial needs. In the second place, it is the lack of stability. The director and all the chiefs of the service change at the will of the ministers, whilst in the private companies the higher personnel is maintained a long time, fulfilling the same functions. It is next the political influence which enters into the choice and advancement of the personnel. It is, lastly, the lack of discipline which also results from the political influence at work. From the electoral point of view, the lower staff, being much more numerous, will always have much more power than the superior staff. It is always on the side of the former that many deputies will be systematically ranged. Above all, it is impossible to be at once controller and controlled. If one of the great French

companies under private management renders poor service, the public opinion is not slow to move the public power, and as this has the means to bring pressure indirectly but in many ways upon the companies, they are led to reform. On the contrary, when complaints are made against the State itself, the administration, irresponsible, does not listen. Rather, it seems indignant that particular individuals or even large associations should dare to find that all is not perfect. 'I have not seen without a certain astonishment,' said the minister of public works, in the chamber, 'the chambers of commerce criticise the actions of the State in its (their) reports upon the railways.' The same minister has dismissed an employee from his office who was at the head of a section of a passenger line which emitted protestations against the delays on the western State service in the Paris suburbs. When the minister was reproached in the Senate, he declared himself ready to do the same again. One may see how dangerous to the liberty of citizens the extension of the industrial régime of the State would be, where the number of functionaries would be indefinitely multiplied and where they would no longer have the right to complain. Mr. County.

"From all points of view, the experience of State railways in France is unfavorable, as was foreseen by all those who had reflected upon the bad results given by the other industrial undertakings of the State, such as telephones, matches, and many others. The State, above all an elective administration, cannot be a good commercial manager. It works expensively, and is powerless before its employees. The experience which we have recently gained has had at least one result. It has provoked a very lively movement, not only against the repurchase of the railways, but against all extension of State industry. This result seems to me fortunate. I hope this opinion will be maintained and that not only we, but our neighbors, may profit by the lesson of these facts."

M. Leroy-Beaulieu gives examples of what has happened under the various heads. "As for formalism and red tape," on the eve of the handing over of the railway to the State there were 1 526 employees in the central office. Within three years the number had increased to 2 587. "The single service of the accountant general was increased by 70 persons directly after the repurchase." And this was partly due to political pressure and partly to excessive red tape. For example, in the Caen Division, the preparation of the pay sheets which, under the company, took 9 persons 3 days = 27 days, under the State administration took 12 persons 6 days = 72 days. "According to official documents, there are not less than 96 persons receiving a salary of more than $1 929.52 in the State system" as against 33 on the system of a neighboring company of much the same mileage, but with much higher receipts. In the 5 years from 1908 to 1912 the total expenditure increased $10 573 770, of which $8 412 707 were for salaries and wages.* In 1908, out of every $19.30 of receipts, the company paid $7.24 in salaries and wages. In 1912 this figure was $9.70. The comparative figure for the five great companies is only $5.70. In 1910, per $192 952 of receipts, the State railways employed 235 persons, the private companies 174.

* The 1912 figures are budget estimates only.

Mr. County.

Again, as the result of the great strike of October, 1910, the Chamber of Deputies voted a large all-around increase in the wages of the staff. Naturally, the staff thought there were shorter cuts to increases of wages than hard work. As a sample of want of ordinary business management on the financial side, the budget commission of the chamber reported that it could not draw up a proper estimate for 1912 from lack of the necessary accounts. "The statements addressed to the budget commission by the administration were manifestly inaccurate. * * * The great part of the statements of receipts and expenditure were found to lack any sufficient justification. Thus, as regards the expenditure upon personnel, the tables accompanying the statement only stated the numbers of workmen and staff and the amount of their salaries in round figures. * * * We wrote for further statements, more particularly the numbers of the personnel. * * * The minister replied (three years after the railway had been taken over) that the enumeration of employees had not yet been made. * * * This example suffices to show the trust that may be placed in the other parts of the budget estimate." This is not the opinion of an outside and unfavorable critic. It is the report of a committee of the chamber of the same political complexion as its predecessor, which voted for the purchase, based upon a draft drawn up by a deputy well known as an advocate of State ownership.

One story given by M. Leroy-Beaulieu is so striking, as a sample of the highest quality of red tape, that it deserves to be given at length. It is from a letter of a station master read in the Chamber of Deputies:

"In the time of the Western Company we station masters had orders to use the rolling stock as quickly as possible and to send to a given station all that we did not ourselves require. Under the State all is changed. Every station master is forbidden to load any wagon without the orders of the distribution bureau of the district. This bureau is, as is well known, a new creation, specially designed for the purpose of finding situations for so many more bureaucrats. Recently, having received two wagons loaded with horses, accompanied by an order to send these wagons to Caen after they were unloaded, I thought to do well by loading in these two wagons 200 sacks of grain, which had been waiting in the sheds for several days to go to Caen. But, alas, I did not know the bureau of distribution. The next day I saw my two wagons return, and I received at the same time an order to unload them. I was reproved into the bargain for excess of zeal. I had to obey the order. That evening I sent the wagons empty to Caen. Next day I received two others, also empty, in which to load the grain."

Mr. Kittredge.

GEORGE W. KITTREDGE,* M. AM. SOC. C. E.—The Society is to be congratulated on having Mr. Stuart speak on the railroad situation, for no other member is better qualified. He has had to do with the construction and operation of railroads, has been connected with the Federal Administration, and is qualified to judge of their requirements and to realize their position.

In reading this paper, before coming to the meeting, the speaker was reminded of the story of the countryman who had been reading

* New York City.

Plato, and said: "I rather like that man Plato; he has got so many of my ideas." Mr. Kittredge.

Mention has been made of the fact that railroads seldom hear from consumers in regard to rates. There may be good reason for this. A rate that is of material benefit to a carrier may have an almost unappreciable effect on the actual price of commodities. For example, an increase in freight rates was asked by the carriers a few years ago, which, if fully granted, would have substantially increased their revenues, and have given them, at that time, a living income. This increase in rates, which meant so much to the carriers, made a difference in the cost of a pair of shoes transported from Lynn, Mass., to Chicago, of one-quarter of a cent per pair.

Emphasis has been placed on the necessity of something being done to take care of unproductive expenditures, such as those in connection with large terminals, and with grade crossing elimination. With a large terminal, like the New York Central, if it were not possible to secure revenue from tenants in, around, and over the station and tracks, the carrier would be very severely affected financially by the enormous expenditures.

Where grade crossings are eliminated, the cost often runs into tens and hundreds of thousands of dollars, and yet it is doubtful if one dollar of added income comes to the carrier by reason of the grade separation.

It costs more to handle a commuter from Yonkers or Mount Vernon through the Grand Central Terminal than the gross amount of money received from that commuter for his ticket, leaving to the carrier the privilege of bearing the expense of housing him at his outlying station and conveying him to and from the city.

On one of the railroads terminating in New York City there are projects being urged for terminal improvements, grade crossing eliminations, and the like, which, if carried out, will involve expenditures of $25 000 000. If some equitable and comprehensive scheme could be devised for taking care of such expenditures as would be unproductive of revenue, those projects might be carried out with benefit, safety, and comfort to the public, giving employment to men returning from military and naval service and war activities, and largely benefiting communities in which such projects are to be undertaken. It is out of the question under present conditions for the carriers to consider such projects. Facts of this sort are not realized as they should be by the public, and Mr. Stuart has done well to dwell on the necessity of making provision in some way for such unproductive expenditures. Such expenditures must be made. They are necessary, from the standpoint of the carrier, as well as from that of the public, and if criticism is to be offered in regard to the amount to be thus expended, it must be that too little, rather than too much, has been expended in this way

Mr. Kittredge.

in the past. Those deeply interested in the railroad situation would do well to give this phase of the subject careful attention.

The welfare of the entire country is intimately affected by the railroad situation. The producer, the shipper, the merchant, the consumer, the investor, and those who prudently try to provide for their families and dependents after their own working days are over; all these, added to the hosts of employees who are necessary in the construction, maintenance, and operation of the carriers, make a vast army of people whose welfare, directly or indirectly, depends on the stability and financial integrity of the railroads. Statements, made in moderation, giving facts and statistics, together with sane discussions such as presented in this paper, are needed and should be encouraged; for the value and necessity of the railroads, and the well-being of the country, are too great to be jeopardized.

Mr. Tomkins.

CALVIN TOMKINS,* ASSOC. AM. SOC. C. E.—The speaker has not had an opportunity to read this paper and cannot discuss it as carefully as he would like. It is fortunate that a gentleman who knows so much about railroads, and who has also had Government experience, has undertaken to discuss the question at this time.

There is no doubt that competition under private initiative, such as we had during the period when our railroads were being developed, is more economical and more efficient in every way than Government ownership and operation; but have we sufficiently considered changed and changing conditions? If there is any way by which the country can preserve the advantages of private initiative, by all means it should do so.

The railroads of the country were developed under the leadership of its brightest minds, by a process of the most intense competition. That competition, consciously or unconsciously, had one end in view, which was the consolidation of the many railroad systems into one. For fifty years steady and obvious progress was made away from many systems toward a few systems, and an unconscious progress toward one system. We have attained the ultimate end of this process of natural selection, and the only reason that the process did not reach its logical conclusion under private control, was because the War intervened and precipitated the end under Government auspices.

The Sherman Law temporarily interfered with the personal consolidation of systems, and prospective bankruptcy stared most of the roads in the face as a consequence of the National policy of starvation which increased expenses without permitting corresponding increase of revenue. The railroads were not permitted to raise their rates, and their living costs kept on increasing. This greatly accelerated the tendency toward failure and ultimate absorption of the weaker by the

* New York City.

Mr. Tomkins.

stronger roads. The War, however, brought out the defects of the system under the Sherman Law, and as these defects became apparent, the separate systems were put under one control for war purposes.

From April until September, 1918, the speaker served as a member of the Inland Waterways Committee, a branch of the Federal Railroad Administration. The Committee made its report as to what should be done with the waterways to help out the railroads, which in the Spring of that year could not carry the freight. Executives were put in charge of the Mississippi River and Erie Canal, and traffic on them was developed.

Not later than September in that year the situation had entirely changed. The consolidation of the railroads and the efficiency of their operation as one system under the best executives, had brought about such a degree of relief that the aid of the waterways was no longer needed. Freight was even diverted from the Erie Canal to the railroads, and there was much criticism in New York State for permitting this and thus limiting the use of the Canal. The principal freight carried on the Canal was grain from Buffalo eastward; and Mr. McAdoo, at that time, acting as the Trustee for the owners of the roads, was protecting them, and properly doing so, against the competition of the waterways.

Mr. McAdoo has asked, since he left office: "What is the use of developing the waterways system of the country if it is to be put back into the old competitive relation with the railroads?" The railroads had virtually succeeded in destroying water competition, except coastwise and on the Great Lakes, and this was necessarily done as a part of the competitive game in which they were engaged.

The situation will in truth be a difficult one for the railroads and for the canals if the old destructive competition is permitted to reassert itself, and the speaker will now ask the complementary question: "What will become of the railroads under such circumstances?" Waterway competition has immense possibilities, which thus far have not been realized. Heretofore, the waterways, and especially the Erie Canal, have been mismanaged by politicians, unprovided with adequate terminals or any reasonable system of prorating with the railroads.

Now that the public is interested in the waterways and highways, there will arise an insistent and increasing demand that there shall be established a fair system of prorating between rail and water commerce, and that the waterways, like the highways, shall be modernized in all respects. If the railroads shall again temporarily go under private control, this waterway competition will without doubt be intensified. The Railroad Administration, which is still very properly acting as Trustee for the holders of railroad securities, has held in check this competition, but if the Government shall in the future encourage full and free competition between quasi private railways, and public water-

Mr. Tomkins.

ways and highways, the result cannot be otherwise than disastrous for the railroads and, the speaker may add, harmful to all three factors.

Any one who has witnessed the volume of traffic on the Rhine and its connecting canals knows the possibilities of waterways, without many locks, such as we have in America and such as exist in Germany. In the speaker's judgment, Government control over these three factors of transportation is essential, if we are to avoid the uneconomic consequences of unnecessary competition. The railroads have also to consider the question of competition with modern highways. A large part of their most profitable traffic has heretofore been the short hauls; but now, any haul over good roads within 50 miles from point of origin to point of destination can be performed more effectively by motor truck than by the railroads handicapped by the intervening transfers.

Existing public sentiment may perhaps be temporarily against Government control, due to recent wartime experiences, but the speaker believes the pendulum will soon swing the other way, since, judging the future by what has occurred, we perceive that a steady progress toward consolidation has characterized the railroad history of our country, which has been a record of exploitations, absorptions, expansions, and bankruptcies, and then the same processes repeated over and over again, the units being larger each time. That is what occurred under the most efficient railroad generalship that has ever been had. It has been the lack of guaranties, lack of any certainty or safety, and the great risks incurred, which in the past made the railroad systems of the United States so effective. All this was accomplished under a régime of most intensive competition. Projects to raise fur on domestic animals have never been successful. It requires the hardship of exposure and wild life to bring out the fur. It is the same way with railroading. It required the law of natural selection, operating freely, to bring to the front the kind of men who developed our railroads, and produced such wonderful results, culminating at last in the greatest railroad system of the world. The competitive conditions which produced these men and these grand results, however, no longer exist. How, then, is it possible to expect to base any system of railroad operation on them? How can we provide competition, when the elements of competition are no longer here?

Are not the proposed "regional systems", equipped with "Regional Directors", in supposed "service competition" with each other, merely camouflaged semblances of the older order of real things which has passed away?

Is not this proposed machinery a mere pretense which may obstruct rather than serve the purposes of operating a national railroad system, already unified?

Are not the proposed regional zones, with their directors, comparable to the several floors in a single department store with their respective floor managers in charge?

Mr. Tomkins.

The Government determines freight rates, wages, hours, schedules, routing, joint operation of terminals and ticket offices, safety devices, issue of securities, uniform accounting and, most important of all, credit—and there is general agreement that these Governmental powers should be perpetuated. What else, aside from the purchasing and allocation of supplies, is there which can possibly be delegated to private initiative? The genius of Commodore Vanderbilt, C. P. Huntington, E. H. Harriman, and J. J. Hill was not exercised under conditions such as those just outlined. The ultimate object for which they, consciously or unconsciously, competed so strenuously, and which has at last been achieved all the more quickly as a result of the War, was a unified system, and railroad competition is now as dead as they are.

A Government guaranty, direct or indirect, to the effect that rates shall be sufficiently high, both to recompense invested capital and to attract new development capital, is, in the speaker's judgment, and under existing conditions, less desirable than will be a public valuation of railroad securities, accompanied with a guaranty of interest based on such valuation. All rate making and responsibility for all expenditures should be left to the general Government which, in the end, must hold the bag, under all suggestions which have so far been made.

A guaranty of payment of interest on outstanding securities is a simple and direct obligation of the Government, easily understood, and, if once undertaken, not likely to be avoided. The delegation of the power to initiate rate making on a basis sufficiently remunerative to provide for all contingencies, and to include a speculative profit in addition, will be a more complicated obligation for the Government to enter into, and one which is much more likely to be avoided in the future. Speculative profits are elusive. Interest payments on railroad securities transmuted into Government bonds are definite obligations.

As to a division of prospective profits between operators and security owners to serve as an incentive to enterprise, the answer is that it is not likely that there will be profits, and, if there are, the operatives will demand them all and probably will get them, to the exclusion of the holders of securities.

The unscientific existing railroad rate structure must be revised. It underlies many of our past railroad troubles, and is the resultant of a variety of forces operating over a long period of time, prominent among which are to be noted the following:

Actual or potential water competition; "what the traffic will bear"; "what was necessary to move traffic", and, finally, equalization of the opportunities and defects of localities.

A juster appreciation of the cost of service and the separation of terminal from line haulage charges must be given greater consideration in rate making hereafter, or the annual railroad deficit may be disastrous. Interstate Commerce Commissioner Robert W. Nolley has ably discussed this matter.

Mr. Tomkins.

The average security owner is as careless of his vote as is the average citizen, and, consequently, ownership, whether public or private, is comparatively immaterial. The roads have always been run, are being run, and will continue to be run, by expert operatives, from the track boss up through the engineering and accounting staffs to the President and the Director General, and the sooner this fact is recognized by the Government and the public and by security owners, the better it will be for all concerned. The quality now most needed for efficient operation is the development of *esprit de corps* in the operating staff, which in time will generate efficiency—not indeed as satisfactory as that which existed before competition ended, nor as bad as politics alone can otherwise make it.

Efficient services rendered to the public, not for bonuses and tips, but for just wages and salaries, in a distinguished and honorable employment, is what the country requires and may ultimately expect from the operating staff.

Absolute security founded on a just basis of values is what the security owner most needs—in other words, a Government bond—and if he delays much longer to press for this, in the hope of securing the elusive chance of higher speculative profits, based on politically delegated control over rate making, he is likely to miss his market.

Mr. Smith.

AUGUSTUS SMITH,* M. AM. SOC. C. E.—The speaker is not a railroad man, and will not attempt to discuss this paper from a railroad standpoint. As a freight shipper, and as a typically insignificant "private owner," if that is what a stockholder or bondholder is called, he does not think that the railroads as a whole have been particularly well run when under so-called "private ownership."

For instance, though the Baltimore and Ohio Railroad has been improving steadily in the last ten or fifteen years (and doubtless a large share of the credit for this must be due to the author), for many years before that, the communities served by it were afflicted by a poverty stricken railroad, and the blighting effects of that condition can be seen to-day in Staten Island.

The list of badly financed, or exploited, and wrecked, railroads in the United States is a long one, and the list of people who have lost money in railroad investments includes nearly every one who has laid aside money since railroads were first started. The New Haven crash will not be forgotten soon in New York or New England. War or Legislative interference had nothing to do with this. It was one of the most "privately owned" of "privately owned" railroads, and seemed to have enjoyed the acme of private management.

The concluding paragraph of the paper states the following fact that every one will endorse:

* Bayonne, N. J.

"The entire matter is of such importance to the whole country that, if this session of Congress cannot settle the question, then an extra session should at once be called for this purpose." Mr. Smith.

We are now faced by the problem of reviving business and sustaining wages. The railroads, in time of peace, are the greatest purchasers of materials and building construction, and hence are the greatest agencies for indirectly employing labor, in addition to their own enormous pay-roll. Their ability to purchase and thus develop their property was curtailed for several years before the war by stringent legislation and by alienated public confidence. The railroads to-day, therefore, present the greatest opportunity for active constructive industry to furnish employment and maintain wages, if they can be promptly put in a position to catch up with their retarded development.

Furthermore, general industry is so dependent on railroad service and railroad rates that any uncertainty in the railroad situation is bound to act detrimentally on the general resumption and expansion of activities.

The author points out the political dangers and the lethargy and stagnation that would probably come with Government ownership, and evidently thinks that "private ownership" with proper regulation and control is to be preferred, notwithstanding the experience we had before the War; but, were it not for the loyal railroad engineers, the "owner" or "owners" of a railroad surrounded by labor unions, Interstate Commerce Commissions, State Legislatures, grade crossing laws, damage suits, lawyers and juries, and represented by financiers, would be in a sorry predicament.

The Federal Government has made great expenditures, and contemplates making much greater ones for the improvement of our inland waterways. It is considering the development of an Atlantic coastal waterway. It has taken over the Erie Canal and the Cape Cod Canal. It has long been in charge of navigation on all tidal rivers and estuaries and on the Mississippi River and the Great Lakes. None of these waterways, except the Great Lakes, can be appreciably utilized for transportation of freight, except in conjunction and co-operation with the railroads. The railroads, hitherto under private management, have deemed it to their own best interests to deny co-ordination with any water-carrying artery, and when it was impossible to throttle and paralyze the movement of water-borne freight, they have deemed it necessary to enter as savage competitors on the water.

The country is now launched on a great shipbuilding programme, and we are wondering how we can get the products of our country and its overseas purchases to and from the ocean and interior in the most economical and expeditious way, quite irrespective of giving the haul and greatest freight return to this or that railroad corporation. We are wondering how our ports should be arranged to reduce the tariff or tax

Mr. Smith.

exacted in the way of transfer expenses at the point of transhipment from rails to the sea.

We have watched for years the growth of interlocking directorates and money interests, whereby the same individuals and corporations are monetarily interested in the railways and in great industries depending on them for an outlet, and whereby, in various ways, such individuals and corporations have obtained an unfair advantage over competitors in special railroad rates and railroad service, and we have tried to remedy this evil by legislation and other makeshifts.

We have long been accustomed to itineraries of carload shipments that remind one of the travels of "The Flying Dutchman". L. C. L. shipments passing over several lines to their destination need not be expected until they turn up of their own accord. In shipping from Bayonne to Boston, for instance, the railroad is not comparable with trucking to New York and then by the steamship to Boston, even at considerable greater expense by the latter route.

We probably are all willing to concede that Federal management of the railroads would mean freedom, or at least equality of land movement—freedom of the land—and would permanently abate the preferential evils we have been trying to reach by legislation.

We may be able to visualize partly the great economic advantages that would ensue if the water routes and the railroads were operated so as to feed each other with business, and if the ports were operated as links in our transportation system, having a duty to perform to the producers and consumers, unmixed with the perquisites of a quasi custom house. Great improvements in handling freight are possible. The rates for carload shipments can probably be reduced. The time for all shipments can be greatly reduced. The suspicion or certainty that some interests get an unfair advantage over competitors in railway service can be done away with entirely.

The railroads are our long-distance highways—turnpikes of the first class. There is no more reason for their being operated by and for the benefit of private individuals than that we should return to the old system of privately controlled turnpikes. Of course, the present owners of these highways must be equitably compensated for their property, and the provisions of the existing contract whereby the Federal Government took over the railways, if the properties are to be retained by the Government, are probably satisfactory to the great majority of holders of railroad securities.

Let us keep before us the conception of a great system of highways owned and operated by the public. We do not need to include every railway in that system, nor do we need to include the operation on such a system of highways of all vehicles by the public. Pullman service, dining cars, refrigerator cars, coal cars, *trains de luxe* for passenger

service, long-distance freight, and all express service could be properly operated over the public highways by private enterprise. In fact, the railroads have been doing this very thing for years with each other, over leased lines, and by leased privileges. All that has to be done now is to let the Government hold the lines, or such of them as seem necessary to the Federal management, and be the landlord. The old railroad men will be available to provide car service. If new lines have to be built, private capital and initiative can be enlisted on equitable terms, and if politicians or self-seeking communities try to have new railroads built at Federal expense, the economic advisability of the proposed construction could be passed upon by Federal engineers, who would be as able and incorruptible as have been the U. S. Army engineers for years past in dealing with our navigable rivers and harbors, holding down expenditures to what would actually be of some benefit to commerce. Mr. Smith.

One of the evils that has impoverished railroads, and that the general public is now going to pay for in the increased transportation charges, is the abuse of grade crossing legislation, mentioned by the author. Baiting railroads has been popular in every State Legislature and town council. If the roadbeds belonged to the Government, grade crossings would be eliminated where necessary, but this would cease to be a political and popular sport.

It might be feasible to have the Government take over with the roadbeds and terminals—that is, with the real estate—the locomotives, train crews, and signal or communication systems. This principle has long been proved practicable under private ownership in the many instances where the trains of one railroad corporation are hauled over the roadbed and into the terminals by the locomotives and train crews of another. Under such an arrangement, strikes threatening interruption of mail service and even starvation for cities could not occur.

If competition is necessary for progress, as the author says it is, it would be possible to have several different corporations competing for business on the same rails, just as the Pennsylvania Railroad and the Central Railroad of New Jersey have competed on the right of way of the New York and Long Branch Railroad for many years. In fact, if the Government chose to put on a car service too, to make a base rate and provide, for argument's sake, a base service, we might rely entirely on competition to regulate the rates charged by private corporations, and dispense with the Interstate Commerce Commission, or at any rate, relieve that Commission of many of the duties it had before the War.

If the Government handled the locomotives and train crews, it would be responsible for train accidents, and some sort of accident compensation, fixed by schedule, would take the place of damage suits, juries, lawyers, and punitive verdicts bearing no relation to the money paid to the railroad by the victims of the accident for their tickets.

Mr. Smith. Finally, the railroads on which people depend for service when they settle in a country and invest their life and money in some enterprise, would be taken out of the stock markets and placed under a guardianship that could not go bankrupt or be re-organized, and that would treat every citizen in every part of the country by the same policy.

Private ownership is a thing of the past. It has long since been a name only. Public ownership exists now. How shall it best be administered? Shall we go back to the fictions and elaborate artificialities of the recent years, made more elaborate by statute upon statute, as one difficulty succeeds another, just as any lie rolls along, growing like a snowball; or, shall we recognize the true relation between control and ownership?

Mr. Bernhard. JOHN H. BERNHARD,* ASSOC. M. AM. SOC. C. E.—Undoubtedly, the author has advanced very valuable ideas on the question of public or private ownership of railroads, and yet it seems to the speaker that the seat of the trouble is deeper than his suggested remedies go. The underlying difficulty in the railroad problem is the rate system.

Using the term in its broadest sense—that of determining the amount to be paid for service rendered—it is evident that, if a satisfactory rate system is adopted, it matters little whether we have public ownership or go back to private ownership; in fact, it seems logical to assume that, with such a satisfactory solution, even the most ardent supporters of public ownership would become lukewarm, unless they were advocating such public ownership for political spoils, and thus disqualifying themselves.

The objection to the private interest is not against men, but against their methods and systems. The public would not be better off with Government ownership under the old system.

The rate problem can be summed up in a very few words: the so-called rate system is no system. It is an impossible fabric of the following principal considerations:

What the traffic can bear;
Anything to beat water competition;
Anything to beat competing lines;
Anything to secure tonnage;
Compromises—increases or decreases in rate based on what some other community has to pay to reach similar destinations, etc., etc.

We have no rate system. It just so happens: that is all that can be said for it. It grew naturally. It is self-made in its worst results. To a great degree—more so in the past than at present—the railroads have, if anything, helped increase its entanglements and its difficulties. Although the United States grew in a most remarkable way, the rail-

* Amsterdam, Holland.

rate system just grew locally, and, later, was patched together, with the result that this rate scheme is based on everything except cost-plus-profit. Mr. Bernhard.

A few illustrations of freight rates may elucidate this: Before the war, in carrying salt from Syracuse to St. Louis, a direct distance of about 900 miles, it was shipped *via* Baltimore, a distance of about 300 miles, reloaded at a cost certainly not less than 30 cents per ton, carried by water to New Orleans, a distance of 1 700 miles, reloaded again at New Orleans, again at a cost of not less than 30 cents per ton, and then carried up by rail to St. Louis, a distance of 700 miles, cheaper than if carried direct to St. Louis. It must be clear that the people as a whole pay somehow for this loss of labor, time, and misuse of investment; and the statement that such a commodity thus carried around may be moved cheaper than in another country is begging the question. The point is that it is moved 1 000 miles by rail and 1 700 miles by water, and handled twice, whereas it could have been moved 900 miles direct, without such rehandling. We should look on foreign countries as our rivals—friendly, perhaps, but rivals nevertheless—and, therefore, we should practice economy as far as we can, and not content ourselves with a statement that as a whole our freights are cheaper than elsewhere. Let us take advantage of our natural resources and not waste them, even if, in the minds of some, we have sufficient margin of profits.

If flour, a difficult article to carry, with its inevitable claims for damages, is carried from New Orleans to St. Louis at a rate per ton-mile which is equal to or less than that at which coal is carried in open hopper cars in Pennsylvania (3 mills per ton-mile), that flour is certainly carried at a loss.

Why should a community which is in the interior and away from water facilities pay frightful freight rates in order that a community on a water route may move its commodities below cost? All "rate differentials" (better called "rate arbitraries"), all comparative rates, all these evils sap our energy.

We have played more or less into the hands of the railroads in the past by creating a ponderous Interstate Commerce Commission, which sits with such great dignity in Washington. To the speaker its top-heavy deliberations often appear as mirror reflections of an imaginary committee which meets for the purpose of discussing carefully how to eliminate or alter a wave in mid-ocean. A commissioner is sent out and the wave is photographed, a bluff is made at measuring it, it is reproduced, a wax model is made of it, and after all data have been collected, the matter is laid before the parent committee, which goes over all the records, finds the center of gravity, buoyancy, specific gravity, has some cuts made, and borings, and determines whether or not it is homogeneous, in order to decide the best and most economical

Mr. Bernhard.

way to smooth out that particular part of the wave, only to find that, after its carefully prepared decision, the wave has disappeared.

It would be very difficult to decide which is the greater evil, the rate systems, the Interstate Commerce Commission, or the conception of transportation by some old-time railroad "pioneers." Unconsciously, the Interstate Commerce Commission has been saturated by that all-penetrating conception of rate-making that the railroads have forced on the public mind and which has permeated America like a chilly fog, blanketing and retarding progress. Although perhaps some members of the Interstate Commerce Commission were willing to remedy this evil, when appointed they are placed in the strait-jacket of the law based on the rate evils, and are not able, laden down with decisions and handicaps, to undertake the David's task of killing this Goliath, even if this Goliath has clay feet.

The speaker has tried to follow the Interstate Commerce Commission, and honestly attempted first to read all its decisions. Then he had to content himself with owning the publications, and now even this has to be given up, unless larger offices are rented to find room for the gigantic library that is turned out of this grist-mill. It is far beyond a shipper, it is far beyond a transportation engineer, to understand that labyrinth. It has become necessary, for a great number of years, to employ special legal experts who devote their lifetime to rates. It is for this reason that every local community, Chamber of Commerce, Board of Trade, Business Men's League, etc., employs traffic managers, traffic commissioners, rate clerks, or whatever their titles may be, for the sole purpose of interpreting rates or trying to get special rates, even if it is at the cost of others—yes, entirely regardless of whether it is at the cost of the United States in general, or any community in particular ("pork barrel" patriotism). It is most customary for one community to try to get the rates of another community raised because they are entitled to a "differential", meaning that, for some reason, born of error and evil, they should be entitled to carry their products into a certain field cheaper than another community. The question of cost of carrying does not enter into consideration.

The proper rate system should be that of terminal charges plus cost of transportation and profit. All railroads should deliver their freight to warehouse doors on sidings, if such exist; otherwise by drays. It is a comparatively simple matter to determine the cost of carrying such freight to and from the proper starting points (freight-yards). Such collection or distribution of freight points to the vital necessity of public ownership of terminals, belt railways, switch-yards, etc. To determine the cost of carrying between terminals is a problem the solution of which is not at all impossible or impractical. In fact, on certainly 90% of the articles carried in America we can determine the cost of transportation very accurately.

Mr. Bernhard.

Of course, the cost of moving freight in certain communities and localities depends on the density of population and on topographical conditions; in other words, if this principle is carried through to its logical conclusion, it will be found that a certain railroad will have to charge a higher rate than a competing line, because the cost over its system would be higher than the cost over others; but, nevertheless, rates should not be maintained below a just level because a railroad cannot get the freight under its correct rates. It is a logical conclusion, and must be accepted on its face, even regardless of results. There is no reason why a shipper in one State should pay a higher rate than cost-plus-profit in order to pay in part for the freight of another shipper elsewhere who pays less than cost-plus-profit. As each community develops, its rates should be reduced.

It is perhaps appropriate to point out: First, that the general statement that freight is carried cheaper in America than in any other country except India is incorrect. It is one of those examples in which statistics lie. The statement is often made that where our cost of carrying is about 7¾ mills per ton-mile in average for the entire country, it is, say, in England (before the war), 22 mills; but the fact is that this 7¾ mills per ton-mile in average is arrived at by including all the freight, 60% of which is agricultural, forest, and mineral products, a very large percentage of such products being moved in France, England (coastwise), Holland, Germany, etc., by water, and, because these low-paying commodities have been left out of their average, such average cost of freight carrying seems to be higher. If, however, we eliminate these three products from the total freight carried, and then ascertain the average for the remaining products, we will have entirely different figures to compare.

Second, it is equally incorrect to state that in the only place in America where the railroads are governmentally owned, the rate, in cents, is more than the average for the privately owned railroads, in mills. The road referred to is, of course, that in Alaska. The question is, what would the rates have been, under private ownership, of a road working under the existing conditions in such a sparsely settled community? The only fair comparison would be with the cost in New Mexico, and even that would be very much in favor of the New Mexico lines, because they at least can operate the year round without snow interference.

Third, the idea advanced by Mr. Smith, on public ownership but private operation of tracks and terminals, has been followed in Holland for many decades, and has worked very satisfactorily.

Mr. Ray.

G. J. Ray,* M. Am. Soc. C. E.—Mr. Smith seems to know something about the Delaware, Lackawanna and Western Railroad and the Cen-

* New York City.

Mr. Ray. tral Railroad of New Jersey. If he lived along the Lackawanna and had looked into the charter of the old Morris and Essex Railroad, he would have found that he has the right to get a buggy, with proper gauge, and, if he complies with the rules and regulations of the road, run his buggy over the Lackawanna as he desires, for the charter of that road, one of the first railroads built in New Jersey, and one of the first in the country, provided that any citizen of the State should have the right to run his buggy over the railroad between Newark and Morristown. He could go on the tracks at any crossing, so long as his buggy was of the proper gauge, if he lived up to the operating rules and regulations of the railroad.

The trouble is that most of our citizens do not want to look up the facts, and do not want to live up to the obligations after they find out what the facts are.

Most of the railroads, especially around New York City, are endeavoring to give the public good service, and have been succeeding fairly well. The speaker believes that if Mr. Bernhard would further analyze the rates in the case he cites, he would find that the salt that went from Syracuse to Baltimore, from Baltimore to New Orleans, and from New Orleans back to St. Louis, was carried at a less rate than it would cost to ship the same salt by rail a distance of from 100 to 200 miles in Germany. Certainly, if all the facts were given consideration, he would not compare the railroad rates in the United States with those of Germany, and, as far as that is concerned, we are doing business here in America now and not in Germany.

There was one point of Mr. Stuart's paper, brought out by Mr. Kittredge, that might be considered a little further, and that is the control of unproductive expenditures required by the public. During the last 10 or 15 years, the railroad with which the speaker has been connected has been spending a lot of money for the purpose of eliminating grade crossings, as well as otherwise improving its line.

Little does the public realize how expensive the commuter business is for a railroad that is so unfortunate as to have to take care of it. That may seem like a more or less ridiculous statement, but an analysis of the facts will show that the railroad that has to take care of a large commuting business, to and from a large center like New York City, has a very serious problem to handle. Where such an immense amount of business is concentrated, especially during such times as we have experienced in the past two or three years, where the capacity of the roads and the shipping facilities have been taxed to the limit, the commuting business is a very grave problem.

The plant required for such a business is necessarily large, compared with the return, and if one considers the total money spent for equipment, terminals, suburban stations, and other expensive improvements,

which are necessary in connection with suburban stations, such as grade crossing elimination work, street diversions, drainage, and sewers, which are always more or less serious problems, it will be found to be very expensive. Mr. Ray.

It takes an immense quantity of equipment, motive power, and cars. The motive power and cars lie idle for the greater portion of the day, for they are used for only two or three hours in the morning and for about the same length of time in the evening. Furthermore, the staff of employees must be sufficient to operate the maximum number of trains. These employees must be paid a minimum wage, and, from an operating standpoint, it is often a difficult matter to use the men to advantage throughout the greater part of the day.

In many cases the suburban business greatly interferes with handling freight to and from the terminals. It cannot be delayed on account of the freight business, and this adds to the cost and increases the delay in handling the freight.

All things considered, as a rule, it is not a very lucrative business, and is one about which the officers and management are criticised almost every day. Honest criticism is all right, and sometimes is productive of good, but, as a rule, the commuter has but little knowledge of the many problems involved, nor does he fully realize the very heavy expenses connected with it.

In rebuilding the stations and eliminating grade crossings in suburban districts, it is usually difficult to satisfy the local commuter and finally convince the people that they are getting the best that has ever been built. Therefore, such improvements are very expensive and bring very little return. As Mr. Kittredge stated, scarcely one additional commuter can be traced to such improvements.

The speaker believes this to be one of the cases in which there ought to be some definite method of controlling expenditures and providing the necessary funds to pay for the improvements, whether through rates or a proper allocation of the expenses.

HERBERT C. KEITH,* M. AM. SOC. C. E.—At present much is heard about conservation, a subject deserving the best thought of all men; but much that poses under that name in the Government operation of railroads reminds one of Aesop's fable of the boys stoning the frogs. It may be fun for the Railroad Administration, but it comes too near being fatal to the traveling public. Mr. Keith.

When Mr. Brandeis, now Justice of the Supreme Court of the United States, stated that the railroads of this country could save a million dollars a day by the adoption of such methods as holding trains until sufficient cars—passenger or freight—were filled to make a train using the full capacity of the locomotive, and running the same at such

* New York City

Mr. Keith.

speed as to procure the maximum hauling capacity of the coal, water, etc., consumed, probably few supposed him to be in earnest. Probably no one believed that the public would put up with the inconvenience such methods would entail; but, under the stress of war, the Government has adopted approximately those very methods, making some saving to the railroads (or their administration), but putting the public to an increased expense of many times the saving to the roads. With the duress of war removed, it is not probable that the public would submit long to such an abuse, whether under Government or private ownership or control.

The number of city railroad ticket offices in Greater New York was reduced to five, requiring a large amount of intra-city travel by the public in order to purchase tickets or to engage accommodations. Even in those five offices the number of employees was reduced to such an extent that the traveler had to stand in line a long time before receiving attention. When purchased, the tickets were good only for the day of purchase; and the sale of mileage books became simply the taking of the purchaser's money by the Railroad Administration in advance, with no benefit to the purchaser, either in cash discount or the saving of later inconvenience; for an exchange of the mileage coupons for the regular passage ticket was required when one was to travel, and at the same price.

The new brand of railroad conservation has been shown, also, in scanty maintenance work, both in way and equipment, so that large expenditures must be made soon, or there will be increased expense, delay, and trouble. Only slightly more than half the normal quantity of rails, ties, and other track material was used in renewals in 1918; stations and other facilities were allowed to get badly out of repair, and almost nothing was done in the way of bridge renewals or repairs. A large number of locomotives and cars were purchased; however, they were not credited to maintenance, but charged to the railroad companies as improvements, though, to a large extent, they were misfits for the different railroads, because the microbe of standardization has attacked the Administration and has led to the purchase of the same kind of rolling stock for mountain roads as for those that have spent millions of dollars to reduce their grades to less than one-half of 1 per cent.

In spite of all this scantiness of expenditure for maintenance of way and equipment, operating expenses have increased 40% above those of the previous year, and the traffic has been substantially the same. This increase of expenditure was due largely to increases in wages of those employees organized in the labor unions, and to the high cost of material and general supplies. Executives, engineers, and other technical men have had no share in this increase, but rather have been dropped, or have had their salaries reduced or thrown on the railroad companies (in distinction from the U. S. Administration),

under the plea that their work concerned the conservation of property rather than the operation of the roads. It is amazing that the cost of such work as the preservation of the title to real estate, reports to and meetings of the stockholders, legal expenses connected with the property, and its valuation as required for the Interstate Commerce Commission, was included in the operating expense in the years on which the compensation to the security holders was based, but such charges were not allowed as operating expenses when making payment—or the promise of such—for the actual use of the property. Mr. Keith.

The agreements made by the Government with the railroad companies call for the return of the property, at the expiration of the period of Government operation, in the same condition as it was received. If this is done, it will require, before that time, for the maintenance of way and equipment, the expenditure of a larger sum of money than the $500 000 000 "Revolving Fund" already used up in the operation.

For years the railroads have been asking permission to make a small increase in rates, but were refused because the Interstate Commerce Commission denied the necessity for such increase to provide a reasonable return on the investment of the stock- and bond-holders. At the same time the Labor Boards awarded increase after increase of wages. A short time before the Government took the roads, a small increase in rates was granted, but this was too late to affect materially the earnings for the period used as the basis for the return to be paid by the Government to the owners for the use of their property. Soon after the U. S. Administration took charge, passenger and freight rates were increased, so that receipts for 1918, for approximately the same amount of business, increased 22% above those for the previous year, but, in spite of this, because of the increased expenses, as previously stated, the net earnings were reduced to such an extent that the $500 000 000 "Revolving Fund" is exhausted, and the Administration asks for an additional $750 000 000 to make up the deficit of what is required to be paid to the railroad companies according to the agreements—even as the Director General himself interprets them.

Demand is now made for five years' continuance of Government operation, because the time has been too short to determine the advisability of Government ownership. One naturally asks "Were the railroads taken for the purpose of aiding in prosecuting the war, or was that only camouflage to conceal Government ownership?"

The subject of rates has been mentioned. It is a very interesting fact that, before the war, in normal times, the railroad companies of the United States paid higher wages and salaries than any other country in the world, while, at the same time, the railroads of this country gave cheaper transportation and better service for both passengers and freight than any in the world, with the exception of India, where rates

Mr. Keith. were a trifle lower, but where the pay of laborers was hardly more in cents than it was in dollars in the United States. It is an interesting fact that on the only Government-owned railroad of the United States, prior to the war, the freight rates were more, expressed in cents per ton, than the average of those of the privately owned railroads of the country, expressed in mills.

In connection with Mr. Ray's remarks about the rights of the Delaware, Lackawanna and Western Railroad, it is interesting to note that the charter of the Boston and Lowell Railroad, granted June 5th, 1830, authorized the company to erect toll-gates at any and all points where it might desire, and to collect the tolls thereat, evidently with the idea that anybody could harness his horse or mule to his car and use it on the railroad. Just before the bill received its third and final reading, an amendment was made, providing that, in case the experiment then being conducted in England should prove successful, the railroad might use steam.

Mr. Williams. CLEMENT C. WILLIAMS,* M. AM. SOC. C. E. (by letter).—This paper is timely, and contains many interesting and valuable suggestions. Dissertations of this sort will assist greatly in securing an economically sane and sound solution of this problem, which affects our industrial organization so vitally.

As the author states, investments in railway securities should be protected, but they should also be removed from the realm of speculation and manipulation. Investments in railroads should be nearly as stable as those in National banks and in Government bonds, if the conditions controlling them were properly adjusted. Such an adjustment, in order to be adequate, must be based on a correct conception of the relative interests of the railway corporations, their employees, and the public, and of the physical conditions affecting the operation of the railroad lines. For example, the author mentions the necessity of controlling unproductive expenditures, such as grade-crossing elimination. Based equitably on an economic distribution of benefits, all such expenditures as grade-crossing elimination, beautification of station buildings and grounds, etc., should be borne largely by the public instead of by the railroads, for the benefits accrue to the public rather than to the railroads or their patrons, and the burden should be placed where the benefits are received. As the benefits of beautified stations and grounds accrue to the local public, their cost should be assessed against them rather than against the railway corporation or against the traveling public through increased rates.

Moreover, such a distribution of expense, in addition to decreasing operating costs, would tend to correct abuses which are of frequent occurrence, for a municipality would think twice with regard to the

* Lawrence, Kans.

necessity of grade-crossing elimination or track elevation before passing an ordinance requiring such work, if it had to pay the bill. Mr. Williams.

This theme of joint responsibilities and benefits leads to a consideration of the entire railway question on such a basis, with a view to ascertaining the proper reconstruction programme as it may pertain to the railroads.

In the reorganization of the railroads, obviously, the aim should be to eliminate the evils of the previous régime of controlled private ownership under quasi-competitive conditions, retain its good features, and add such further provisions as will render the railways better adapted to the needs of the nation. The outstanding general defects that existed in our railway administration previous to the leasing of the lines by the Government are:

1.—Stock watering and other phases of unsound finance;
2.—Lack of stability in railway securities;
3.—Inefficiency and waste through lack of co-operation due to competitive jealousies;
4.—Cumbersome, conflicting, and ineffective control by State and Federal authority;
5.—Disregard of the rights of the public in matters pertaining to service and in labor controversies.

The meritorious features of private operation have been demonstrated to be:

1.—Economy and efficiency in operation resulting from placing actual responsibility in the operating officers, rather than having them act merely as agents for an extraneous bureau;
2.—The initiative that results from local responsibility;
3.—The gain derived from direct dealing and the absence of red tape that seems to be an inevitable concomitant of governmental administration;
4.—The freedom from harmful interference in administration due to the influences commonly designated as "politics."

In addition to avoiding the evils and retaining the advantages of private operation and ownership listed above, the purpose of any new measures should be to:

1.—Effect a more complete realization of the unity of interests among railway companies, their employees, and the public;
2.—Give adequate Federal control over rates and financial policies;
3.—Adjust the railway systems and groupings on the basis of optimum service to the nation as an entity in meeting its transportation requirements, making provision for pooling and direct routing of traffic.

Mr. Williams.

So far, the only solutions of the railroad problem commonly advocated are a complete return to private ownership and operation after the expiration of the Government lease, on the one hand, or ownership and operation by the Federal Government, on the other. Inasmuch as either of these arrangements is admittedly open to serious objection, it may be wise to cast about for another scheme, with a view to obviating the defects and securing the desirable features of both. There is no law or reason compelling one of these plans to be adopted *in toto* exclusive of the other. Certain situations have arisen in the railroad world within the past few years that may suggest a general scheme for the solution of the difficulty, although the final adjustments would doubtless have to be made as time might reveal the need.

The experiences under the past mode of administration and under present Governmental operation, as well as some other experiments that have been tried in the field of railway transportation, seem to indicate that the plan which is most likely to secure the objectives mentioned above is a median course between private ownership, on the one hand, and Government ownership on the other, a plan that would bring together into a partnership the parties involved, and harmonize and unify their interests. The principles underlying such a partnership are suggestive; hence, an outline of the main features may be considered with profit.

In the first place, the railways would serve the needs of the country most effectively if they were organized permanently in a comprehensive manner, designed to meet the transportation requirements of the whole nation as an entity. A state of development has now been reached in which the centers of population are fixed, the character and location of the main fields of industry are determined, and, consequently, the transportation requirements of the future may be reckoned chiefly as a normal growth and development along the lines already established. It is time, therefore, that a comprehensive transportation system is designed to meet the conditions as they exist now and may be predicted with reasonable certainty for the future. An effort is all the more opportune at this time, when the railway situation is to be made over, when, in a sense, "the cloth is uncut", for now the railways can be regrouped boldly according to the economic requirements of the country, unhampered by any existing artificial financial alliances. The leasing and operating of the railroads by the Government has given a new point of departure and an opportunity for a comparatively fresh start in formulating a railroad policy, and advantage should be taken of this fact to plan boldly and without prejudice for fitting the railway transportation to the economic and industrial situation.

In order to secure the advantages of direct routing and of pooling equipment and similar methods of operation which the present régime

Mr. Williams.

has demonstrated to be advantageous, the railways should be grouped permanently into regional systems and incorporated under holding companies. Such regional systems should follow the natural traffic groupings, instead of artificial and arbitrary regional assignments as made by the Director General, or even those of the Interstate Commerce Commission. Such a plan, of course, would be based on a thorough statistical study of the natural traffic routes, and would necessitate a carefully studied classification of roads into trunk lines as main arteries, subsidiary lines, and feeders, with a view to construction, maintenance, and operation as such.

The major financial policies of such large companies as just suggested could best be regulated by the Federal Government holding a controlling share of the stock. Under such an arrangement, no stock watering or other fraudulent procedure could be carried out without Government sanction, and hence action by the Government could be secured before the harm was done. One of the defects inherent in the previous methods of governmental control has been that the nefarious schemes of stock manipulation were completed and the damage to securities was done before the Government was aware of what was happening, and before the governmental machinery could be got into motion to prevent it. The result has been that it was a case of "locking the barn door after the horse was stolen." Laws were enacted which illegalized a repetition, but did not prevent a similar thing from being done in a different way. With the Federal Government holding a controlling interest in the stock, however, it would necessarily be apprised of any contemplated action of this sort.

A ready means of stabilizing railway securities under such a scheme of organization would be to issue the Government's stock as junior to the privately owned stock, making it the first to meet assessments and the last to receive dividends. Perhaps the Government might hold practically all the common stock. Such a preferential payment plan would establish railway securities on a firm basis without the necessity of guaranteeing returns on private investment by the Government. Making the stock owned by the Government junior to the privately owned stock would work no injustice to the Government (provided, of course, that the limits of preference were equitably adjusted), for the Government, as a social community, would receive benefits in other ways than in returns on stock, *viz.*, reliable transportation, diminished fluctuation in industry, wider range of industrial and social activity, increased land values, etc. The information obtained by the Division of Valuation of the Interstate Commerce Commission would be of service in such a reorganization. A board of directors, under such an arrangement, might properly be composed of representatives of the Government, representatives of labor, and representa-

Mr. Williams.

tives of private capital. Beyond the board of directors, the operation of the lines should be entirely under private control.

Much has been said of the rights of the public, as affected by the railways, in regard to the character of service rendered, inconvenience and loss during labor controversies, etc., but there has been no apparent inclination on the part of the public to share the responsibilities of operation. This attitude is not in accord with sound economics, for rights and responsibilities should go hand in hand. By entering into a partnership, the public could control the general policies of the railways and thus protect their rights, and, at the same time, share their proportionate responsibilities. For a similar reason, employees should be encouraged by some means to hold railroad securities.

Examples of organization similar to this plan may be mentioned as partial illustrations of the principle involved. The National Railways of Mexico, constituting somewhat more than half of the total mileage of the country, are organized on a basis similar to that just described. Of the total issue of stock of $224 000 000, the Mexican Government owns $115 000 000, which includes all the common stock, about one-third of the first preferred, and about one-sixth of the second preferred. The National Railways cover practically the entire country, and form a network articulating with the other railways. All shares of the National Railways have equal voting rights, although the preferred stock has the right to elect five directors separately. The Mexican Government guarantees the principle and interest of the general mortgage bonds, although any payments made by the Government under this guaranty are to be repaid out of net profits otherwise distributable as dividends with interest at 4%; and this repayment takes precedence over all dividends except on first preferred stock. The Government has come to the aid of the railways about six times under this arrangement. All dividends are tax exempt. The result is that the railways are about the most stable feature of that country.

A similar scheme of organization exists in New York City whereby the city and the electric railways within its borders have formed a partnership for further providing the city with transportation facilities. In financing the Dual Subway plan, the City of New York is to furnish $171 000 000 and the railways involved $166 000 000 for the extension of the subways. The stock owned by the private parties is to receive preferential payment of dividends, taking precedence over municipal stock. This scheme is economically sound, for the city as a community receives benefits from possessing an adequate transportation system which may be properly set off against the dividends received by private stockholders.

In such a scheme of organization as described above, the railways become essentially "operating companies" rather than "owning companies." Under the present governmental administration, a definite

distinction has been drawn between the officials representing the corporate interests and those concerned with operation. Moreover, Government-owned munition plants, shipyards, and other properties have been placed in the hands of "operating companies" during the past two years. The idea, therefore, of an operating company is not entirely new, but has a more or less recognized status in the present industrial organization. Private operation has been demonstrated by experience all over the world to be superior to Government operation, provided the abuses of private ownership can be eliminated, and should be retained, therefore, if possible. Mr. Williams.

Summarizing: The present situation is such as to afford an opportunity for re-grouping and reorganizing the railways of the country according to a comprehensive design adapted to the economic needs of the country as a whole, and steps should be taken to obtain expert determination of these economic requirements as related to the railways. To avoid the defects of private ownership, and, at the same time, obviate the inherent faults of Government operation, the most promising arrangement seems to the writer to be the formation of a partnership between the Government and the railways. This appears to be preferable to the more or less inimical control on the part of the Government, which has tended to stifle development in the past, and to discourage legitimate investment in railway securities. Moreover, it is only by an appreciation of the community of interest of the public, and of the railways, that the economic welfare of the country as affected by the railways can be realized.

C. A. Morse,* M. Am. Soc. C. E. (by letter).—The writer would like to call attention to one of the statements in this paper, which he fears is too sweeping and may lead to misunderstanding. Mr. Stuart states: Mr. Morse.

"Some of the things which were ordered with propriety during the war, which should be undone at once and not five years hence, are: * * * an immediate abandonment as a national effort of an attempt at standardization of all manner of railroad necessities and methods."

This might lead to the impression that there was under way, at present, an attempt at standardization of all manner of railroad necessities and methods, which is not the case.

There were numerous committees at work during the war, under the War Industries Board, in an attempt at general standardization. Their work, however, was shut off as soon as possible after the signing of the armistice, and no such national effort at standardization is being undertaken by the United States Railroad Administration.

There are, however, without doubt, many things that could be standardized with advantage to every one. One of the most important

* Chicago, Ill.

Mr. Morse.

of these is standardization of rail sections, and of the location of bolt-holes in rails. At present, there are nearly fifty different sections of rail between 70 and 136 lb. per yd. Notwithstanding the fact that the American Railway Association and the American Railway Engineering Association have recommended as standard only seven sections between these limits, practically every railroad has a different spacing for bolt-holes, and there is a great variation between the location of the center of bolt-holes as regards the neutral axis of the rail. Standardization of rail sections and of the drilling of rails is a very desirable thing to accomplish.

The fact that the standardization of methods and appliances has been found to be a source of economy on the larger railroad systems, thereby reducing the stock of materials necessary to be kept on hand, plainly indicates that, could this be extended to the railroads of the country, it would mean economy in manufacture, which, in the end, would mean reduction in the cost to the railroads and the public.

One of the dangers in standardization, however, is the idea expressed in the last portion of the paragraph in the paper from which the foregoing quotation was made, that standardization to some people implies that an approved standard means a perfected article. There is no reason why standardization should limit, in any degree, efforts to improve devices or to adopt new standards at any time when an improvement in a standardized article has been perfected.

The writer agrees with Mr. Stuart that wholesale standardization is a dangerous proposition, but he feels that standardization used with judgment has a broad field for economy.

Mr. Whinery.

S. WHINERY,* M. AM. SOC. C. E. (by letter).—It is clear that public opinion is strongly opposed to exclusive ownership and operation of the railroads by the Government; and there is a strong body of opinion opposed to their return to private ownership under the same status as before the war. Some scheme seems to be generally favored under which ownership and operation shall be in the hands of the private or corporate owners, with adequate Governmental power of control in certain important respects. There is, however, much difference of opinion as to the extent and details of the powers which the Government should exercise.

The difficulties likely to be encountered in a dual scheme operated by independent parties would doubtless develop from the diverse and often antagonistic views and interests of the three parties involved—the owners, the Government, and the public.

If some plan could be evolved under which these three interests could be unified and harmonized to a great extent, with a competent

* New York City.

and disinterested tribunal to adjudicate such differences as might arise, a distinct approach to the ideal would be attained. Mr. Whinery.

Can a practical working project of this general character be devised?

The question is worth consideration and discussion, and, as a contribution to discussion along such lines, the following suggestions are submitted:

The controlling features of the scheme suggested are:

1.—Joint ownership of the railroads by the corporate owners and the National Government;

2.—The operation of the roads by the corporate ownership;

3.—Control by Governmental agencies of certain important functions, such as general financing, basic policies, co-ordination of operating plans, and supervision of rates;

4.—The creation of a tribunal having ample authority to adjust differences that might arise and be referred to it.

A brief outline only of the suggested scheme can be here undertaken. If the general project has merit, the details should not be impossible, and perhaps not very difficult to work out.

1.—Congress should enact the necessary legislation, requiring all railroads to be incorporated under the United States Government and embodying all necessary provisions for carrying the plan into effect. Among these would be:

2.—The creation of a tribunal of mediation and control, of last resort (except to the Supreme Court), to which questions not otherwise adjusted could be referred and adjudicated. This tribunal might be a commission like the Interstate Commerce Commission, with enlarged but well-defined powers, or a Department of Transportation, the head of which might be a member of the Cabinet.

3.—The acquirement by the National Government of a safe controlling interest (ownership) in the leading railroad systems and important independent lines of the United States, by the purchase of shares of stock in the open market, or, if necessary or advisable, by the exercise of the right of Eminent Domain. In the latter case, shares should be taken from shareholders in proportion to their holdings over, say, five shares; the purpose being to preserve as wide a distribution of privately owned shares as possible.

4.—Unless conditions should arise making it necessary to do otherwise for the public good, the secondary or less important roads would not be included in the scheme; that is, they would remain wholly in the ownership and control of their corporate shareholders. These less important roads have been, and would continue to be, influenced, directly or indirectly, by the policies and practices of the more important lines with which they connect.

Mr. Whinery.

5.—Provide that the boards of directors or controlling bodies of the jointly owned roads or systems shall each consist of an uneven number of directors, a bare majority of whom, to be known as Government directors, shall be appointed by the President of the United States, while the minority shall be elected in the usual manner by the private shareholders—the Government shares not to be voted at such election.

6.—The functions and duties of the board of directors to be divided into two general classes:

a.—All matters in which the Government may properly exercise supervision and control; such as capitalization, general financing, controlling policies, combinations, consolidations, competitions, apportionment of earnings, and the making and general supervision of rates; also, the appointment of presidents or chief executives.

b.—All matters relating to the practical operation and management of the roads, including construction and maintenance of road, equipment and plant generally; the appointment and control of all subordinates and employees, the primary making and adjustment of rates, schedules of operation, etc., and generally of all matters not specifically named in Class *a*.

7.—In all matters coming under Class *a* each member of the board would be entitled to one vote, and all members of the board would stand on an equal footing. In all matters coming under Class *b* each Government director would be entitled to one vote and each corporate director would be entitled to two votes. The result would be that in all Class *a* matters the Government directors, being in the majority, would be able to exercise control, while in all Class *b* matters the corporate directors, by reason of their dual votes, would have a controlling voice.

8.—The Government directors should be appointed for life, subject to removal for cause, and should devote their whole time to their duties. Each should serve on the directories of a number of different roads in the same region, or having common, related, or competitive interests, thus making the boards, in a measure, "interlocking" in character.

9.—Any differences that might arise between the two classes of directors, which they were unable to adjust, as to their respective rights or duties, or the interpretation of laws, or general policies, would be referred to and decided by the supreme tribunal, subject to review by the Supreme Court.

10.—The principle that railroad rates shall be such that the shareholders shall receive a fair and just return on their investment, should

be recognized and made mandatory by the basic law. Rates should be fixed and adjusted by the directories of the roads subject to review and modification by the tribunal, wholly independent of Congressional action; but earnings or dividends should not be guaranteed by the Government. Mr. Whinery.

11.—State or local commissions or officials should be authorized by the law to exercise, only, usual or necessary police powers and local control in purely intrastate questions. Their status with reference to the railroads would be substantially the same as in the case of navigable rivers.

The enactment of the necessary and appropriate legislation by Congress to carry out this—or in fact any other—general railroad plan, would be a work of prime importance, requiring careful study and foresight. Its provisions should be definite and clear, as full and detailed as practicable, but, at the same time, permitting such latitude and elasticity as would allow and foster enterprise, initiative, and efficiency in the management of the properties.

The Government directors, of course, should be men of high character and special fitness for their duties, and the method of appointing them reasonably might be expected to secure such. Life appointment, as in the case of Justices of the Supreme Court, should remove them from the sphere of political influence.

Some of the merits and advantages of such a project, properly administered, are obvious, but they may be briefly outlined:

1.—The joint ownership, and resulting common interest in the properties, of the corporate shareholders and the Government, representing the interests of the public, would tend to remove or neutralize the spirit of distrust and antagonism that has been, particularly in recent times, one of the most discouraging features of the railroad situation. The participation in the management of able men, representing the interests of the public, with no private, partisan, or political ends to serve, with power to control in all matters in which the Government or the public it represents might properly intervene, should secure in large measure the respect and confidence of the people.

2.—The practical result would be to secure all the benefits of Government ownership combined with those of private operation.

3.—The interlocking feature of the boards, by which the Government directors would serve on and be distributed among the directorates of a group of roads with related interests, would give them opportunity and facilities to acquaint themselves with all the facts and conditions of the situation, and they would be in a position to permit or direct such combinations and adjustments of routes, rates, interchanges of business, and apportionment of earnings, etc., as might seem just, and best for the interests of all concerned.

Mr. Whinery.

4.—Although the necessary investment by the Government would be large, the means could be provided by the issue and sale of bonds at a comparatively low rate of interest, with the certainty that its share in reasonable dividends would greatly exceed the interest charges. A surplus should result which would be a dependable source of large revenue for public purposes, to that extent relieving general taxation of the public.

5.—The purchase of the Government interest in the railroads would release a large amount of capital to the corporate shareholders, to be reinvested in other industrial or business enterprises.

6.—Such a project, when once properly organized and installed, should be permanent in character and results, subject only to such minor changes and improvements as experience might prove to be necessary or desirable.

7.—One of its most important results should be to remove effectually our troublesome railroad problems from the sphere of partisan politics.

It may be objected to this plan that boards of directors composed of two distinct classes of men, representing different interests, would not be likely to work together harmoniously; but, in fact, they would represent the same and not different interests, as the purpose of all would be to secure and promote the efficient and successful management of the railroads for the benefit of all the shareholders as well as the public. If, for instance, rates and earnings were made too high, the public would share in the surplus through such lower general taxation as the Government earnings would permit; if too low, the public would be called on in the same way to share a part of any resulting losses.

It is obvious that, if such a scheme proved to be practical and successful in the case of the railroads, it might, with some modifications, be applied to the control of the great industrial businesses that are commonly regarded as monopolistic, and in need of some governmental regulation.

Mr. Stuart.

FRANCIS LEE STUART,* M. AM. SOC. C. E. (by letter).—So much has happened since the paper was published, so much wandering of ideas, so many plans discussed, so many bills proposed, and so little accomplished that in closing the discussion it is impossible to more than touch on some of the fundamental aspects of the case.

Private capital, with expectation and hope of gain, built the railroads which have made the United States great. The amount of capital so invested can be dissipated by public policy, or the mistaken judgment of either capital or labor, but if so dissipated, new capital for further progress in this line will have to come from taxation, and will be spent on a partisan political basis instead of on the financially sound basis of an expected return on the investment.

* New York City.

Mr. Stuart.

Government ownership, in spite of propaganda in its behalf, seems to be still more impractical and unthinkable than it did in January, 1919. The readjustment demands of the times urgently require that the Government return the roads and set in motion this return and the relinquishment of other abnormal functions that it assumed during the war.

The railroads have lost their credit, and before they can stand alone their financial standing must be rehabilitated by a law enacting broad constructive policies and by the extension of Government credit, in order that money may be procured until such policies actually show that they are beneficial. The only way that private investors can be induced to put their money into the jeopardy that their past investments in railroad securities have been placed, will be the assurance and visible evidence of a continuing policy which will give a fair return on the average railroad, efficiently operated.

Innumerable plans have been presented and discussed, and a number of bills have been proposed, for solving the railroad question. They all shed light and may be illuminative, but, individually, the writer thinks that if Congress will turn the roads back with a proper emergency rate and with the necessary protection of Government credit, the next few years could be well spent by Congress, not in passing new bills, but in repealing a large part of the existing law on the railroad subject and in codifying the remainder so that it can be understood by the public.

The fundamental principle of American business, in fact of all business, is to charge what the traffic will bear, be it a railroad or a corner grocery shop, and supply and demand governs the application of this law. The Government has found it necessary for the benefit and protection of the public to create general laws to regulate business, which are applicable also to the railroad business. On account of the public character of the railroads, in addition to such general laws of the land, there should be special laws, governing safety, preventing discrimination and unreasonableness of rate, and requiring reasonable service. The greatest factor in making such laws really effective is the preservation of competition and reward for initiative. With these incentives many new laws now in existence could be repealed.

If the prohibitive laws which now prevent the consolidation of railroads under certain conditions were modified, a natural consolidation of a number of properties would follow, a consolidation based on competitive reasons and on business standards of a return on the investment so made. The writer doubts whether a Federal consolidation of all railroads into one, or two, or ten, or any stated number of systems, not based on competitive reasons, would eliminate more than $200 000 000 of duplicated capital investment and, for the sake of eliminating this comparatively small amount, we would be bartering

Mr. Stuart.

away our birthright of competitive service on $20 000 000 000 of capital invested in our railroads.

On account of the difference in conception and in the conditions of the various railroads, some will prosper on a given rate while others will fail, but, in the writer's opinion, it is unconstitutional—or should be—for the Government to guarantee a fixed amount of return on the investment in railroad securities and not do the same thing for the coal business or the wheat business or for any other industry dealing with the necessities of life—any of which could be made bankrupt of credit by the same treatment which has been given to the railroads in the near past.

It also seems to be unconstitutional—or it should be—for the Government to give to labor or to capital or to any class or community any amount earned by the properties over and above a fixed return on the capital investment. If any such profit should legally accrue to the Government, it should be spent by the legislative powers for the benefit of all the people.

The reward for initiative and sound judgment should be maintained and the average railroad allowed to prosper as a right and not by sufferance. Railroads must pay their way from day to day, and become a reasonably prosperous self-sustaining factor in our communities, or they will become a dangerous political canker.

The political temper of these readjustment times, combined with other causes, seems to have prevented constructive work by either political party, and the results at least make it doubtful if it is wise for Congress with its present mental attitude to try to pass remedial legislation under the present abnormal conditions of capital, labor, and Government functions.

Why not, then, pass simple legislation, providing for an extension of credit and a fair emergency rate? The roads should be returned to their owners at once and as an emergency act the railroads should be extended credit by the Government and given a fair emergency rate to help them over the readjustment period through which the country has to pass.

A fair emergency rate, in the writer's mind, is the present rate properly increased so that when applied to the units of transportation making up the revenue tonnage of all the railroads, it would in the aggregate pay operating expenses and leave an amount over and above the gross operating expenses of all the railroads to be applied as remuneration for the capital invested in all the railroads, such remuneration to be in keeping with the current value of money and be divided among the roads as earned by service.

The Railroad Administration has been in charge of railroad accounting figures, and a percentage to add to the present rate could easily be found. There should be no discrimination in the application of

such an emergency rate. Each road would earn as much of the gross amount as it could in competition with the other roads and as a reward for efficient service, and yet American competitive business methods and standards of pre-war times would be maintained and the result would be fair to the greatest number of the population. Immediate action is needed, and it does not require months to establish such a rate, for if the rate should prove too high in a few years, and if the political feeling of the time should require it, a graduated excess profit tax as a post-war measure could be applied to the more prosperous roads, until during normal times a more equitable rate could be found. Such excess profit tax could be used, as all similar taxes should be used, for a direct reduction of the war debt. Mr. Stuart.

Paper No. 1447

GROUTING OPERATIONS, CATSKILL WATER SUPPLY*

By James F. Sanborn† and M. E. Zipser, Associate Members, Am. Soc. C. E.

With Discussion by Messrs. Robert Ridgway, J. Waldo Smith, Lazarus White, John P. Hogan, Francis Donaldson, Waldo C. Briggs, A. J. Sackett, Andrew A. Cohill, A. J. Mayell, Milton H. Freeman, C. L. Riker, Jr., Benjamin A. Howes, Theodore Belzner, and M. E. Zipser.

Synopsis

Grout was used extensively in the structures of the Catskill Water Supply System for filling spaces behind the lining of tunnels, for cutting off the flow of water into shafts and tunnels by grouting the water-bearing fissures, for solidifying the foundations and stopping the flow beneath dams, and for various other purposes. The object of this paper is to give a summary of the experience and results obtained in the use of grout in the construction of the aqueduct, dams, and other structures of the Catskill Works, with the hope that it may prove valuable to those undertaking work involving grouting.

Grouting was one of the important operations in the construction of the pressure tunnels of the Catskill Aqueduct. These tunnels, forming about one-third of the total length of the Aqueduct, are subjected to great hydrostatic pressures when in service, and it was essential

* Presented at the meeting of February 4th, 1920.
† Now M. Am. Soc. C. E.

to make them tight against outward leakage. To prevent the escape of water, grouting was depended on to back up the concrete lining and to close all open seams in the rock adjacent to it. The Aqueduct has been in service for two years, and the slight and practically negligible loss of water from the pressure tunnels is evidence of the complete success of the methods adopted in their construction.

To prevent the percolation of water through porous zones under the Ashokan and Kensico Dams, extensive grouting was done, the grout being forced into the rock seams under air pressure through holes drilled into the ledge rock underneath the dams. To cut off the leakage which had developed underneath the foundations of the two earth dikes at the Ashokan Reservoir, and to improve the foundations, holes were drilled through the core-walls and rolled embankment into the rock and grouted.

Grout was also used to cut off the flow of water during shaft sinking and tunnel driving, in order to permit the work to proceed more rapidly and reduce the expense of pumping. Considerable grouting was also done in connection with repairs in parts of the Rondout, Breakneck, and City Pressure Tunnels, where the lining had been ruptured when the tunnels were subjected to working pressures. The breaks in the lining were due to the yielding of the rock when the test pressures were applied, and grout was injected to fill the cracks in the rock surrounding the tunnel.

Other uses for grout on the Catskill Aqueduct included the lining of large steel pipe lines, the grouting of stretches of poor ground in grade tunnels, the filling of the expansion joint openings in the cut-and-cover aqueduct, and for other purposes. In some of these cases, the grout was not forced in by air pressure, but was placed by pouring or by means of a hand pump.

Grouting in Pressure Tunnels.

The utilization of the pressure-tunnel type is one of the notable features of the Catskill Aqueduct. There are nine pressure tunnels, aggregating 35 miles in length. These tunnels were driven in rock, deep beneath the surface, and were lined with concrete averaging from 18 to 24 in., and more, in thickness. They have a finished inside diameter varying from 16 ft. 7 in. to a minimum of 11 ft. The depths of the tunnels below the surface vary from 100 ft. to a maximum of more than

1 100 ft., the latter being the depth at the Hudson River crossing. The hydraulic gradient at this crossing is more than 1 500 ft. above the invert of the tunnel. The pressure-tunnel type was adopted only after extended study, as there was no precedent for such tunnels subjected to such high unbalanced heads.

It was the opinion of some authorities that the concrete lining could not be made tight enough against ground-water heads. It was also feared that where the rock was porous and water-bearing, excessive leakage might develop when the tunnel was put in service, and that the application of pressure in the case of jointed and fissured rocks might even cause movement of the rock and rupture of the concrete lining, with resultant outward leakage. Great reliance, therefore, was placed on the use of grout to make the tunnels secure and tight against all leakage.

Design of Pressure Tunnels.—On account of the heavy internal hydrostatic pressures, it was deemed advisable to place the tunnels under a heavy cover of sound rock. This cover is not less than 150 ft., except in the case of comparatively light heads. On account of the external ground-water pressure on the tunnels when they were under construction, or at any time when they are out of service, the circular shape was adopted, and the lining was made thick enough to withstand both the ground-water head and the grouting pressure necessary to overcome frictional resistance and ground-water head. The concrete for the lining was proportioned, mixed, and placed so as to be practically water-tight. The concrete lining, in addition to preventing outward leakage, also provides a smooth coating to produce a high coefficient of flow. It also prevents the falling of rock and makes easier the cleaning of the tunnel.

As it was practically impossible in lining the tunnel to pack the concrete tightly against the irregular surface of the rock in the roof, grout was forced in to fill all the voids over the arch and back of the lining and to transmit the internal pressures to the rock. It was expected also that the grout would be effective in closing the seams and crevices in the rock surrounding the tunnel by impregnating any porous, water-bearing strata so as to cut off all subsequent outward leakage.

Conditions Encountered During the Excavation of the Pressure Tunnels.—Before the contracts for the pressure tunnels were let,

FIG. 1.—COMPLETED PRESSURE TUNNEL IN NEW YORK CITY.

FIG. 2.—WET HEADING IN CITY TUNNEL, SOUTH OF SHAFT 4.
A FLOW OF 300 GAL. PER MIN. CUT OFF BY GROUTING.

extensive borings were made to develop the rock profile in the valleys to be crossed and to ascertain the kind and condition of rock to be encountered during the driving of the tunnels. The tunnels penetrate a wide range of geologic formations, the rocks varying in character from a soft shale to hard quartz conglomerate. The most important quality, however, from the standpoint of water-tightness of the tunnel, was the soundness and tightness of the rock to prevent outward leakage.

In stretches where the tunnels passed through faulted and crushed zones, and the rock was either unsound or structurally weak, steel ribs and lagging were used to support the roof. At these places the space between the steel lagging and the rock was packed with stone, the dry packing being subsequently grouted through 2-in. pipes set in the concrete lining and extending into the dry packed space.

Although the pressure tunnels were excavated several hundred feet below ground-water level and under rivers and streams, there were only a few stretches where an excessive quantity of water entered during the excavation. In many stretches the tunnels passed through blocky ground intersected by joint planes and crevices; the openings in the rock at these places were often found to be filled with deposits of mineral matter, and little or no water entered the tunnels through such openings. Several of the tunnels passed underneath glacial gorges, and the drift overlying the rock formed a dense impervious blanket against the inflow of water. With the exception of the wet stretches of tunnel, to be described in detail later, no cases of inward leakage occurred during the excavation exceeding 150 gal. per min. per mile of tunnel. In the 18 miles of the City Tunnel, the maximum quantity of water which entered the tunnel, was 137 gal. per min. per mile.

The geological conditions in the tunnels were given careful consideration, as the structure of the rock, the nature of the openings, and other conditions influenced the method of grouting. Underground water circulates in the rock through the intersecting joint planes and seams formed by bending, folding, and faulting due to disturbance of the earth's crust. Stratified rocks are often found with alternating hard and soft layers, some of which are quite porous, permitting free circulation either through the body of the rock or along the bedding planes. Vertical planes of fracture are of frequent occurrence in stratified rocks. In the Helderberg limestones large solution cavities

or mud seams were encountered, requiring special precautions in making the tunnel secure and providing against subsequent outward leakage.

All inflowing water from the rock seams was taken care of before placing the concrete lining by collecting the water and leading it through pipes set in the concrete, as will be described later in detail. Subsequently, the water-bearing fissures were grouted through these pipes. In many cases, the inward leakage during excavation gradually diminished and often stopped after some interval, due to the discharge of accumulated water in the seam, but the points of inward leakage and the areas of general seepage were carefully noted when the excavation was first made. The locations of wet seams were recorded, and provision was subsequently made for grouting at these places, as it was realized that when the tunnel was in service, water could escape through the same channels whereby it had entered.

Grouting the Rock Seams During Tunnel Driving to Cut Off Leakage Into the Tunnel.

Where large flows of water are encountered in driving a tunnel, a loss of progress invariably results, and very often the work is shut down until additional pumps are installed for handling the water. Obviously, it is of great advantage, where the inflow is very heavy, to reduce or cut off the leakage, if possible, before the heading is advanced. As a rule, however, superintendents dislike to stop excavation and grout the wet ground, preferring to continue the driving, if possible. Several efforts were made on this work to cut off the water by grouting the rock during excavation.

Wet Stretch, Rondout Tunnel.—In driving up a 15% incline north of Shaft 4, in the Rondout Tunnel, a faulted and crushed zone in High Falls shale and Binnewater sandstone was encountered, yielding a considerable flow of water charged with H_2S gas. To shut off the water, an attempt was made to solidify the rock in advance of the excavation by grouting through the drill holes in the heading which flowed water. These holes yielded a flow of about 300 gal. per min. They were closed with pipes and grouted, but the high pressure used—200 lb. per sq. in.—blew off 3 ft. of the soft shale in the face of the heading. Additional holes were drilled around the periphery of the tunnel and grouted. Although the leakage was somewhat reduced, the

flow increased with the advance of the heading, as additional water-bearing seams were encountered.

On account of the heavily faulted and crushed condition of the shale, which was intersected by wide and narrow seams, it became apparent, after further efforts, that grouting could not be depended on to reduce the leakage materially, and it was then decided to advance the heading without further grouting. After a suspension of nearly three months, during which time a pumping plant having a capacity of about 5 000 gal. per min., was installed in the tunnel, excavation was resumed. The first shot revealed a large water-bearing crevice to the right of the tunnel yielding about 600 gal. per min. Numerous other leaks were encountered as the heading was advanced, the total pumpage reaching a maximum of about 2 000 gal. per min. The inflow of water subsequently gradually diminished to about 1 000 gal. per min., remaining nearly constant at this figure until it was finally shut off by grouting after the lining was placed.

Better results might have been secured in this stretch if a concrete bulkhead had been used to retain the grouting pressures, although the soft and weak condition of the rock was very unfavorable for grouting. Another reason for failure to cut off the water under the conditions encountered was the difficulty of adjusting the consistency of the grout to both large and small seams. Large seams require thick grout for thorough filling, while thin grout must be used to fill the fine seams. Ordinarily, the consistency of the mix was adjusted to the large seams which have to be filled first. In order to secure the best results, grouting of the large seams should be followed by re-drilling and grouting with fine grout, to fill the narrow seams.

Grouting Water-Bearing Seam, Hudson Tunnel.—In excavating the Hudson Pressure Tunnel, 1 100 ft. below the river surface, a flow of about 500 gal. per min. was encountered in the heading near the East Shaft. A 4-in. pipe was first put in the hole from which most of the water issued, and concreted in place. The pipe was connected to the discharge line in the shaft, and the water was forced by its own pressure to a pump chamber at the side of the shaft 300 ft. above the bottom. Eight horizontal holes were drilled into the heading and plugged with pipes fitted with valves. A concrete bulkhead, 5 ft. thick, reinforced with steel rails, was then built against the face of the heading, the pipes extending through. About 180 bags of neat

cement in grout was then forced in through the pipes under pressures up to 700 lb. per sq. in. The grout was mixed in a Canniff tank and was discharged by displacing it with water pumped in by a high-pressure plunger pump.

On shooting the heading after the grout had set, there was no increase of water even after passing the seam, which was a narrow, clean-cut, vertical crack crossing the tunnel nearly at right angles and found to be well filled with grout. When the bench was excavated, exposing the seam in the bottom, it appeared to be filled with grout, but after it had been excavated about 13 ft. beyond the point of original leakage, one of the vertical bench holes struck a flow of 110 gal. per min. This flow disappeared after the next shot, and it is supposed that the hole was plugged by the displacement of the rock. The open condition of the seam in this tunnel made it easy to grout, particularly as a tight bulkhead was provided, retaining the pressure. The rock was firm and hard, and the walls of the fissure did not contain soft rock, which would have blocked the opening and prevented the free entrance of grout.

Grouting in Pressure Tunnels After Placing the Concrete Lining.

With the exception of the two instances just described, where an attempt was made to grout the rock seams at the time of driving, all grouting in the pressure tunnels was done after the concrete lining had been placed. As already suggested, the purpose of this grouting was, first, to fill with grout all void spaces between the concrete lining and the rock so that the internal hydrostatic pressures might be transmitted to the rock without rupturing the lining; and, second, to prevent or reduce the leakage out of the tunnel by forcing grout, under pressure, into the water-bearing crevices in the rock and by impregnating any porous rock surrounding the tunnel.

Placing the Concrete Lining in the Pressure Tunnels.—The concrete lining in the pressure tunnels was placed in three steps: First, the invert or bottom strip, from 4 to 6 ft. wide; second, the side-walls extending up to, or a few feet above, the horizontal diameter; and, third, the arch comprising the upper part of the section. The invert was placed continuously, with joints at the end of the day's run, which averaged about 125 ft., while the side-walls and arch were con-

creted in lengths depending on the lengths of forms used, varying from 40 ft. to a maximum of 150 ft. Steel forms were used for the side-walls and arch, the concrete being shoveled behind the forms from platforms resting upon these forms. When the concrete in the arch had nearly reached the top, longitudinal boards were set radially on either side of the top arch plate, and the concrete was banked up on a slope above the boards. Before placing the concrete in the key of the arch, the radial boards were removed and the concrete was shoveled in place in the key by end handling.

The concrete for the tunnel linings was mixed approximately in the proportions of 1:2:4 in the pressure tunnels north of New York City. The mix, however, was varied as the requirements of the work demanded. In the City Tunnel, a 1:1½:3 mix was adopted. Portland cement was used in all parts of the work. A moderately wet or plastic mix was used for the entire section, except near the top of the arch, and in the key, where a drier consistency was adopted.

Protection of Concrete from Inflowing Water During Placing.—In order to secure a dense, tight lining, it was considered essential to protect the concrete, while it was being placed and during the time of setting, from running water. The method generally adopted to accomplish this purpose was to place tin or galvanized-iron drip-pans against the rock so as to collect the water and keep it away from the concrete during placing and setting. The water from the pans ran into the tunnel through weepers, consisting of 2-in. steel or wrought-iron pipes set in the concrete while it was being placed, the pipes being extended through the steel forms by holes cut in them.

In cases of concentrated flows, holes were drilled into the rock seams and pipes were set to collect the water without the use of drip-pans, or, in some instances, both deep-seated pipes and pans were used. All flowing pipes and spaces behind the drip-pans were subsequently grouted. The drip-pans were usually held in place against the rock by nailing the edges of the pans to wooden plugs set in holes a few inches deep drilled for the purpose, and by bracing them from the forms. The space between the edges of the pan and the rock was carefully caulked with oakum or plaster of Paris, or a mixture of cement and plaster of Paris, to prevent the concrete from getting behind the pan and plugging the weeper.

In placing invert concrete, the water-bearing seams were taken care of by placing over them broken stone drains covered with cement

bags or sheets of tin, and placing grout pipes so as to have them extend down through the invert concrete and drain. Wherever necessary, the water was kept below the top of the broken stone drain by pumping through one of the grout pipes until the concrete had set sufficiently hard. In other cases, longitudinal pipe collectors were laid under the invert, carrying the water to a sump from which it was pumped. There were cases of small springs in the lower part of the side-walls, where drip-pans could not well be placed. At such places, the grout pipe was run to a blind drain made of broken stone and covered with empty cement bags and dry concrete.

The drip-pans varied in size from 1 or 2 sq. ft. to a maximum of, perhaps, 150 sq. ft. It was found to be better to use several small pans rather than one large one, in order that the grouting pressures might be applied more directly and thus be more effective in closing up the seams, and also to avoid possible rupture of the lining upon the application of the high-pressure grouting. The pans were usually fitted with two pipes, one at the bottom to drain the water and subsequently for grouting, and the other near the top to act as a vent and aid the circulation of the grout in the pan. Small pans were frequently fitted with only one pipe. A great deal of care and attention was given to the placing of the drip-pans and pipes in order to insure a tight concrete and, in addition, to make adequate provision for effective grouting subsequently.

In order to make it unnecessary to cut many holes through the forms for the pipes, it was intended originally to arrange the piping back of the forms so as to use a system of collectors with a few holes cut in the forms at regular places. It was found to be more effective, however, to use short, direct pipes for grouting purposes. There are several objections to grouting through long pipes with bends and other connections; namely, the danger of clogging the pipes, the impossibility of cleaning out the pipes or of drilling through holes already grouted for the purpose of regrouting, and the delays likely to occur in placing an arrangement of pipes with complicated details.

With the steel forms first used, holes were cut for the grout pipes and weepers only where necessary, and after repeated use, the forms were badly cut up. On some of the later work, holes were cut in the forms at standard locations. On one contract there was a threaded hole at the center of each plate, to which the pipe could be secured. This

provided an opening for each 15 sq. ft. of surface, which was adequate for ordinary conditions.

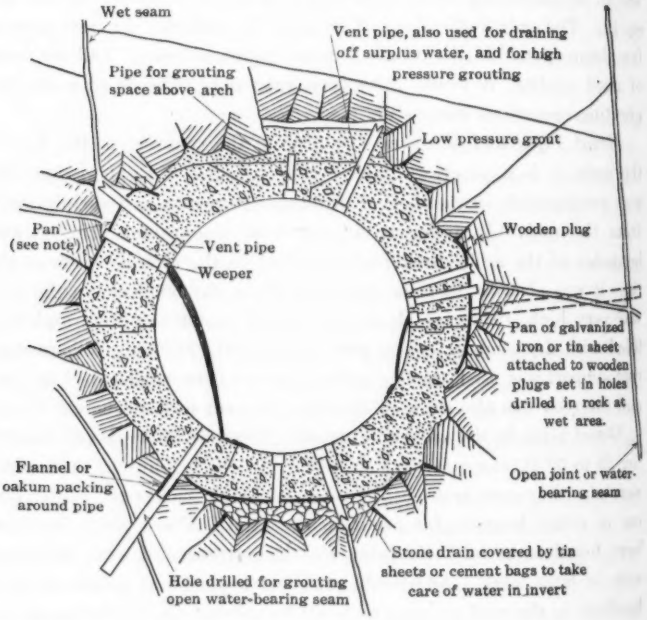
By the methods adopted for placing the concrete and protecting it from inflowing water, during setting, a dense concrete of excellent quality was obtained for the lining of the pressure tunnels. In a test made in the Wallkill Pressure Tunnel, the lining for a stretch of 180 ft. of ungrouted tunnel was subjected to a pressure of 135 lb. per sq. in. The only indications of seepage through the concrete were a few damp spots. If the concrete in the pressure tunnels had not been of good quality, it would have been extremely difficult to make the grouting operations successful.

Grout Pipes and Weepers.—In placing the concrete in the key of the arch, it is a practical impossibility to pack it tight against the rock continuously in the roof. Furthermore, in setting, it shrinks away from the rock. In order to fill the void space along the top and haunches of the arch, grout pipes were set in the arch concrete at the time it was placed. In some stretches, where the breakage in the roof was very high, the space above the normal thickness of the arch was filled with dry packing which was subsequently grouted. Where steel roof support was used, the dry packing placed between the steel lagging and the rock was also grouted through pipes set in the concrete lining.

Grout pipes in the arch were usually placed at intervals not exceeding 25 to 50 ft. along the dry stretches. In the beginning, three pipes were placed at each transverse joint in the arch, one at the center and one at either haunch, for grouting the joint. These pipes, however, were found to be of little value for the purpose and were dispensed with in later work. Additional pipes were placed at points of high breakage in the roof to serve as vents to prevent the formation of air pockets and insure the complete filling of the voids.

Both weepers and grout pipes were 2-in. steel or wrought iron, except in one of the tunnels where 1½-in. pipes were used. The 2-in. pipes are preferable as they do not clog as readily as the smaller ones. The grout pipes were carefully placed and were usually wedged between the forms and the rock, either with a spike or other spacer at the end near the rock. Each pipe was provided, at the end nearest the form, with a standard coupling to which the hose connection was made for grouting. On some parts of the work, a wad of oakum was placed in the end of the pipe nearest the rock, in order to keep out the concrete.

Upon removing the forms it was the usual practice to clean out the pipes by poking a rod into them. To prevent the displacement of the pipes during concreting, it was the practice in one of the tunnels to extend all pipes, the dry ones as well as the weepers, through the forms by means of nipples screwed into the couplings. The nipples had to be removed before the forms were struck.



Note:

Water flowing into the tunnel from the seams in the rock is collected behind drip pans, and drains into the tunnel through 2″ pipes set in the concrete while the latter is placed. The concrete is thereby protected from running water during setting. The 2″ pipes are later grouted. Holes are also drilled in the rock before placing concrete, to intercept water-bearing seams. These seams are subsequently grouted through 2″ pipes placed in the holes as shown.

PRESSURE TUNNEL
IN WET SEAMY ROCK
METHOD OF TAKING CARE OF INFLOWING WATER AND MAKING PROVISION FOR GROUTING WATER-BEARING SEAMS
JUNE 12, 1918

FIG. 3.

Low and High-Pressure Grouting.—Grouting in pressure tunnels was done in two stages: (1) Low-pressure and, (2), high-pressure grouting. The purpose of the low-pressure grouting was: (*a*) primarily to fill the void spaces between the lining and the rock, particularly above the arch, and, at the same time, to form a blanket over the construction joints in the arch; (*b*) to fill the voids in the dry packing where the latter was used; and (*c*) to fill any porous or honeycombed spots in the concrete.

The object of the high-pressure grouting was: (*a*) To cut off the leakage of water into the tunnel and thereby prevent the escape of water out of the tunnel by filling with grout, forced in under high pressure, the crevices and openings in the surrounding rock; and (*b*) to complete the filling of the voids between the lining and the rock, particularly in the high places in the roof, and between the drip-pans and the rock. In general, the procedure followed in grouting was first to grout the space above the arch under low pressure through the pipes set for the purpose, and then to grout, under high pressure, the vent pipes and weepers.

Low-Pressure Grouting.

Detailed Description.—The details of the low-pressure grouting differed somewhat on the various contracts, the following description being typical of the procedure as finally developed. When a stretch of tunnel was ready for grouting, the usual practice was first to grout the arch pipes, beginning at one end of the stretch and working toward the other. The pipe to be grouted was first raked out in order to clean it of any obstruction; sometimes, it was blown out with air to clear it. Plug cocks were placed on all pipes to which connections were made. A 2-in. grout-hose connection, equipped with a side vent, was attached to the pipe to be grouted, and batches of grout from a tank grouting machine were then discharged through the hose and into the pipe, by compressed air. The pressure ordinarily used for this grouting was about 75 to 90 lb. per sq. in.

Grouting was continued at each pipe to which connection was made until the pipe refused to take more grout or until the grout had traveled along the roof several hundred feet ahead, when connection was made with another pipe and the process repeated. The distance which the grout above the arch could be forced ahead of the pipe,

varied from 200 to 300 ft., and, in some cases, where there was a large continuous void space in the roof, it would travel more than 500 ft. It was the usual practice, however, where conditions were normal, to grout the space above the arch by making connections to the roof pipes every 125 to 200 ft.

In charging the grout tank the cement, sand, and water in proper proportions were placed in the tank, and the air was allowed to boil up through the batch to agitate it, while, at the same time, the batch was generally stirred by a hand paddle, as the air alone was insufficient to mix the materials thoroughly.

As the batches of grout were forced into the pipe and the grout flowed ahead, water in large streams issued from the adjacent roof pipes; this was the excess water from the grout, as well as the ground-water leakage which had collected above the arch. This water was pushed ahead of the grout, and as soon as the pipes showed a flow of grout they were plugged either by driving tapering pine plugs into them or, as in the case of the vent or other pipes to which connection was to be made for high-pressure grouting, they were closed by means of the plug cocks at the ends. In some cases, the holes for the connections were plugged by driving a wad of oakum back into the far end of the pipe. At the end of the shift, or several hours after grouting, when the grout had partly set, the oakum was removed with an auger. Any pipe which had filled up with grout that had set, was drilled out for the subsequent grouting.

During low-pressure grouting, the high vent pipes were kept open to drain off the excess water, to permit the escape of air, and to prevent the accumulation of ground-water pressure. During the grouting, the transverse joints in the arch and any porous spots in the concrete generally showed a seepage of water first, then very thin grout appeared, after which, the leaks usually stopped in a short time, and silted up. In some cases, the leakage of grout and water through the joints was stopped by driving thin wooden wedges into the joints, and leakage through the porous concrete was stopped by bracing and wedging a board covered with a mat of oakum against the porous spot. The longitudinal joints on either side of the key at the top of the arch also leaked in a few stretches, due principally to porous concrete in the vicinity of the joints.

The weepers from drains and drip-pans, and the deep-seated pipes were also kept open during low-pressure grouting. The matter of proper venting and free drainage of the ground-water during low-pressure grouting is of the greatest importance in securing good results, because it is essential not to permit the building up of a ground-water head on the fresh grout since the object is to form an impervious blanket over the top of the arch and thereby prevent leakage of water through the unset grout and the formation of channels through the transverse and longitudinal construction joints or through any porous spots in the concrete.

Grouting Dry-Packed Spaces Above the Arch.—When grouting dry packing in large void spaces above the arch, hose connections were first made to the lowest pipes, and as the voids in the dry packing were filled and the water was drained off, connections were made to the higher pipes. Cases occurred where the vent pipes extended from 15 to 20 ft. in the dry packing above the arch, and, at these places, grouting was continued until the vent pipes showed a flow of grout, indicating that the dry packing was thoroughly filled. Where water is present above the arch, it is important that the grout should displace the water from below and not be permitted to mingle with it. Samples cut from the grout above the arch showed the grout to be exceedingly dense and impervious, filling the space without shrinkage and often forming a close bond with the surrounding rock.

Proportions Used for Low-Pressure Grouting.—A batch of grout consisted of one bag of cement weighing about 95 lb., one bag of sand weighing generally about 80 to 90 lb., and from 6 to 8 gal. of water, the total making a batch of about 2.0 to 2.2 cu. ft. of liquid grout measured in the tank. The cement was the ordinary commercial brand used for the concrete lining. The sand was very fine, screened when necessary to meet the requirements of the specifications, namely, that 100% pass a sieve having 64 openings per sq. in., 45% pass a sieve having 1 600 openings per sq. in., the wires of the sieves being, respectively, 0.035 and 0.013 in. in diameter. In the work north of New York City, glacial sand was used, while for the City Tunnel white quartz beach sand from the south side of Long Island was obtained.

The quantity of grout placed depended on the excess breakage in the roof and the extent of the dry packed spaces. In the City Tunnel, in unsupported stretches, where no dry packing was used in the roof

the quantity of grout placed under low pressure varied from 4 to 9 cu. ft. per lin. ft. of tunnel.

Progress in Low-Pressure Grouting.—The progress in low-pressure grouting varied, usually from about 600 to 1 000 ft. of tunnel a week, working three shifts a day. Many factors influenced the speed, such as the length of haul, the delivery of materials, the proficiency of the gang in loading and unloading the cars, etc., and, of course, the volume of space to be filled above the arch. Usually, in normal stretches of tunnel, not more than one or two connections were made in 24 hours. The sand and cement were hauled through the tunnel to the grouting plant on flat cars holding from 20 to 30 bags. The sand was brought to the work in bulk, but was bagged by hand at the top of the shaft before it was sent underground. Tests were made of handling the sand in bulk in the tunnel, but it was soon found that a package of about the same size and weight as a bag of cement was the most convenient form for rapid handling.

The force employed in the tunnel for low-pressure grouting was generally one foreman and seven or eight men, two charging the grout tanks, one stirring the batch, one operating the valves on the grout tank, and three or four handling the hose and making the connections. On the surface, men were employed to bag the sand and load the cars on to the cages.

Precautions to Be Observed in Placing Low-Pressure Grout.—Low-pressure grout should be injected gently under as low a pressure as possible to avoid churning of the mix and separation of the ingredients, and only a sufficient quantity of water should be used to produce a freely flowing mixture that will not clog the hose. The air pressure should not be higher than necessary to force the grout through the hose and into place. A reducing valve was used on some parts of the work to cut down the line pressure from 90 to 40 and 30 lb. per sq. in. An excess of air, especially when injecting grout under water, is likely to agitate and churn the mix, causing separation and stratification of the sand and cement, with the formation of a soft deposit of laitance at the top of the grout in contact with the rock.

To avoid the after blast of air when grouting a space filled with water, it was the usual practice to close the discharge valve before the hose "kicked", the latter requiring careful watching. A further precaution used to prevent the separation of the mix where a large

space filled with water was grouted, was to keep the grouting connection from 2 to 3 ft. below the top of the grout.

The importance of venting the high pipes and allowing all the weepers to run freely during low-pressure grouting has been referred to. It sometimes happens that low-pressure grout enters the drip-pans or drains, but in such cases the pipes should not be kept closed to allow the accumulation of ground-water pressures.

In stretches showing general seepage in the roof of the tunnel, taken care of by drip-pans and pipes, it was sometimes found that the panning was not entirely successful in preventing the water from mingling with the grout. At first, it was thought that these wet stretches should not be grouted with the drier stretches on either side, and they were skipped on the first trip, but it was found that better results could be secured by grouting the wet stretches in the roof with the rest, as the water in the wet stretches did not accumulate pressure, but would travel over the top of the dense unset grout to open vent pipes, sometimes a long distance away, instead of breaking through the grout blanket at a point of near-by weakness.

High-Pressure Grouting.

The purpose of the high-pressure grouting, as already stated, was to complete the filling of the voids between the lining and the rocks, and, more particularly, to cut off the flow of water into the tunnel by forcing grout into the water-bearing seams and closing up all openings in the surrounding rock, in order to prevent or reduce the leakage out of the tunnel when the latter is in service.

Detailed Description.—It was the general practice first to grout the high vent pipes in the roof, in order to complete the filling of the space above the arch, and then to grout the pipes from the drip-pans and the deep-seated pipes leading to the rock seams. Some of the vent pipes in the roof showed a flow of water in stretches originally dry. The grouting of one vent pipe would often stop the flow of water from another, indicating a flow of grout through the open seams in the rock. In other cases there would be an increase in the flow of water from a weeper due to forcing water through the rock seams to an open vent. As a rule, very little grout could be injected into the vent pipes.

After grouting the arch pipes, the "wet" pipes, or weepers, were next grouted. In starting operations, air at 100-lb. pressure was

Gauge measurements of the rock-water pressure were often taken before the grouting of a flowing pipe was started. The gauge readings, however, gave no clue as to the quantity of grout the pipes would take. The gauge pressures showed that the rock-water level at the pressure tunnels had dropped considerably below the original ground-water level, the gauges registering pressures usually under 100 lb. per sq. in., so that the back pressure was not generally high and the grout was forced in under high net pressures. In many cases, the entire ground-water head was restored a few weeks after the completion of the high-pressure grouting. The grouting of a wet seam in the Hudson River Tunnel has already been referred to. At this location, the ground-water pressure before grouting was 475 lb. per sq. in., and the grouting was done under pressures running up to a maximum of about 700 lb. per sq. in.

Mix and Consistency.—To insure the flow of grout into the fine openings, neat cement was used in high-pressure grouting. The consistency of the mix varied, depending on the conditions. Ordinarily, 1 bag of cement and 5 to 8 gal. of water were used. Where grout could be forced into the rock seams it was mixed very thin—as thin as ¼ bag of cement to 30 gal. of water. If this mix was taken freely, it was regarded as an indication that the grout was traveling some distance from the tunnel lining and, therefore, was not of much value. The mix was accordingly thickened gradually by increasing the quantity of cement in the batches until the pipe began to refuse grout, when thin grout was again injected, the pipe being finally plugged with a batch of thick grout under 300-lb. pressure.

Cement.—It was originally contemplated to use very finely ground cement for grouting in order that the grout might be carried readily into the finest seams. However, cement of ordinary fineness of grinding was used, as it was realized that, in time, the openings outside the tunnel lining and through the body of the concrete would silt up. Experiments show that the finer the grinding, the greater the loss in the strength of the grout on account of the more thorough hydration of the cement. The coarse particles impart strength to the cement, and, for that reason, very fine grinding may not be desirable. Some tests were made under severe conditions, using quick-setting Lias lime, but the results were not satisfactory, as the material did not harden properly and the water was not cut off.

Precautions to Be Observed in High-Pressure Grouting.—A very important factor in successful grouting is the control of the consistency of the mix. For large openings, thick consistencies should be used, while for the very finest openings the best results are obtained with thin grout. The thick mixes, however, must carry enough water to prevent undue clogging. No coarse particle or lumps of cement must be allowed to go into the tank. The cement is sometimes affected by the dampness of the tunnels and should be screened when necessary. Grouting of a hole must be continued without an interruption long enough to clog the hose or permit an initial set of the grout.

Special Features in Connection with Grouting.

Time Required for Grouting and Quantity of Grout Placed.—The time required for grouting the pressure tunnels varied, depending on the method and equipment used, the length of haul, the extent of the space grouted, and the quantity and distribution of inward leakage. Table 1 and the following data give the progress, force employed, power consumption, and other facts relating to the grouting in the two miles of tunnel included in Section 8 of the City Tunnel, in the lower part of New York City. This portion of the tunnel was comparatively dry, there being no large, concentrated flows within the two miles. The air used for grouting was supplied by a compressor at the top of one of the shafts. The plant and equipment used for grouting on this part of the work are shown in Fig. 6.

Finished Diameter of Tunnel, 11 and 12 Ft.

	Low-pressure grouting: One grouting outfit.	High-pressure grouting: One grouting outfit.
Linear feet of tunnel grouted	10 313	10 313
Connections to grout pipes	170	1 683
Eight-hour shifts worked	72	116
Batches of grout placed	23 298	2 888
Quantity of liquid grout placed, in cubic yards	1 761	153
Quantity of grout per linear foot of tunnel, in cubic yards	0.17	0.02
Progress per week, in linear feet of tunnel	2 690	1 467

The total force employed in the tunnel and on the surface, averaged 42 men on each shift during the low-pressure grouting and 34 men per shift on high-pressure grouting, for two grouting outfits.

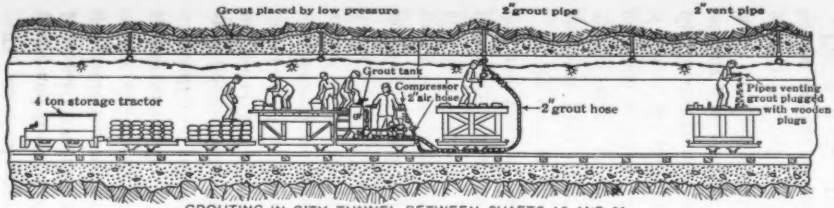
The electrical power consumed by the compressor, hoist, lighting, pumps, and tractors aggregated approximately 7 800 kw-hr. and 5 300 kw-hr. per 1 000 ft. of tunnel on low and high-pressure grouting, respectively, covering two grouting outfits.

The cost to the City, of grouting, based on contract prices, averaged $5 per lin. ft. of tunnel, on Contract 67.

Quantity of Grout Taken by Flowing Pipes.—The quantity of grout injected into the pipes varied, depending on the flow of water, the size of the openings in the rock, the back pressure, and other conditions. The quantity of water issuing from a flowing pipe gave some indication of the quantity of grout the pipe would take, but it was not an absolute index. An idea of the quantity of grout taken by flowing pipes is furnished by the experience in grouting seams in limestone in the Rondout Siphon, where the tunnel lining was ruptured on account of movement in the surrounding rock when the tunnel was first filled with water for the purpose of testing it. Holes were drilled through the lining into the rock, and the seams were grouted. A very thin grout was used—about 0.8 lb. of cement to 1 gal. of water.

In the case of 29 pipes flowing less than 1 gal. per min., only 6 took more than 1 bag of cement, and the maximum in any one pipe was 2.5 bags. Of 24 pipes leaking from 1 to 5 gal. per min., the maximum quantity of grout injected into any one pipe was 24 bags of cement, the minimum, 0.25 bag, and the average, 4.3 bags. Of 12 pipes leaking from 5 to 10 gal. per min., the maximum quantity injected into any pipe was 7.5 bags, the minimum 1 bag, and the average 3.2 bags. Of 8 pipes leaking more than 10 gal. per min., the maximum quantity injected into any one pipe was 198 bags, the minimum 5 bags, and the average 62 bags.

Cut-off Walls.—The method of grouting originally contemplated called for the construction of masonry cut-off walls to be built over the tunnel arch tight against the roof, at intervals of about 50 ft. The purpose of these walls was to confine the flow of grout and to grout the space above the tunnel arch in short stretches, the pressure in the stretch grouted being raised gradually until the maximum required pressure of 300 lb. per sq. in. was reached. It was expected that the high pressures would force the grout into the seams in the surrounding rock. The cut-off walls were to be constructed so that they would retain grout under the maximum pressure.



GROUTING IN CITY TUNNEL BETWEEN SHAFTS 19 AND 21

SECTION

GENERAL DESCRIPTION

The operation of grouting the tunnel was divided into two distinct stages: Low-pressure grouting and high-pressure grouting. The object of the former was primarily to fill the space at the top of the arch left by the shrinking of the concrete away from the rock and to fill openings at joints and honeycombed places. The object of the latter was to fill open seams in the rock surrounding the tunnel and all pipes and pans placed to control water seeping into the tunnel.

LOW-PRESSURE GROUTING

Each unit consisted of a grouting car equipped with two grout tanks, one cement car, two platforms on wheels, six flat cars, two electric storage tractors and three shifts of men. Air at a pressure of 100 lb. per sq. in. at the shaft compressor was used in the machines at a pressure of 95 lb.

Only pipes located in the key portion of the arch were connected to in low-pressure grouting.

The grout hose was connected to pipes situated at points where the rock roof was low; pipes at high points acted as vents. As grout flowed along the top of the arch, first water appeared through joints between successive days' work and from grout pipes embedded in the arch; this water was followed by grout which became thicker and thicker and finally clogged all leaking joints. All pipes running grout were stopped with wooden plugs and the valves on key pipes were closed.

In low-pressure work the hose was connected directly to valves on key pipes instead of on the Y-branches shown. Grout was forced ahead 100 to 300 ft. before the machine was moved to the end of the grouted portion. The standard low pressure batch was 1 bag of cement, 95 lb. of sand and about 7 gal. of water. This batch made 2.04 cu. ft. of liquid grout or 1.92 cu. ft. of set grout.

HIGH-PRESSURE GROUTING

Twenty-four hours after any section of tunnel had been grouted by low pressure, all pipes which were to be connected to were cleaned out to rock to allow effective treatment by high-pressure grouting.

Each unit consisted of one grouting car equipped with one grout tank and one booster compressor, one cement car, two platforms on wheels, three flat cars and two electric storage tractors and generally one shift of men. Air was delivered from the shaft compressor to the booster compressor, which raised the 95 lb. pressure to 300 lb.

High-pressure grouting was accomplished generally in one trip over the section of tunnel. The grout hose was connected to the pipes by a Y-branch, as shown, to allow a rod to be forced in for the purpose of freeing a passage for the grout which often became jammed in the pipes by the high pressure.

All grout pipes that were connected to had grout forced into them at 300 lb. pressure, which was maintained for 5 min. The standard high-pressure batch was 1 bag of cement and 5.5 gal. of water, which made 1.24 cu. ft. of liquid grout or 1.2 cu. ft. of set grout.

FIG. 6.—METHOD OF GROUTING IN PRESSURE TUNNEL

In the beginning efforts were made to build these cut-off walls, but, after some experience, it was found to be impracticable to make them tight against the high pressures. Aside from this consideration, there is serious objection in the case of wet stretches to dividing the arch into short sections and at once applying high-pressure grout. If the ground-water is confined, the head builds up, and on the application of high-pressure air to the liquid grout over the arch, the ground-water will force an outlet into the tunnel through the transverse construction joints in the arch. Efforts to stop such leaks by drilling holes in the concrete lining and rock and subsequent grouting were generally unsuccessful.

After the originally contemplated method of building the cut-off walls was abandoned, an attempt was made to build grout cut-off walls and to grout in three stages, substantially as follows: A connection was made to a pipe set at a low spot in the roof profile, and grout was forced in under low pressure, generally from 30 to 40 lb., until it flowed from an adjacent pipe the upper end of which was at a higher elevation. Another low spot in the roof, about 75 to 100 ft. distant, was then grouted, and the process was continued throughout a stretch of tunnel. If any weepers showed grout during this stage, they were plugged, and the holes were reopened about 12 hours later by cleaning out the pipes with a rod. Subsequently, connection was made at these holes for high-pressure grouting.

After the grout cut-off walls had set up, the second stage consisted in grouting the sections between the cut-off walls, starting with a pressure of 100 lb. and raising it to 300 lb. per sq. in. The high vent pipes were then opened and the water which had accumulated was allowed to run off. After a stretch of tunnel had been grouted in this manner, all the valves at the ends of the pipes were opened, all plugs removed, and all pipes which were open and flowed water, were grouted under a pressure of 300 lb. After this method of grouting had been tried, it was found that more than 70% of the total quantity of grout placed was used for forming the cut-off walls. There was therefore little or no advantage in this scheme, and it was abandoned, and the method of grouting the entire space above the arch in one operation without the use of cut-off walls, as already described, was adopted.

A fair degree of success was attained in the use of cut-offs in one stretch in the Rondout Tunnel, where the shrinkage space between the

concrete in the arch and the rock in the roof at the end of each section of arch was packed tight with mortar. The method of grouting was to fill the space above a section of the arch with 1:1 grout at a pressure of about 50 lb. per sq. in. and, after this space was filled, to continue forcing neat cement grout through the same connection until the hole refused to take grout at 300-lb. pressure. High vent pipes in the same section of arch were then grouted under a pressure of 300 lb. per sq. in. The conditions in the stretch where this method was used were very favorable, the arch being practically dry and the breakage in the roof regular. Not all the cut-offs proved to be tight, however, and the grout was not confined in all cases. An interesting test, showing the reduction of tank pressure, was made during the grouting in this stretch. With an air pressure of 300 lb. per sq. in. at the grouting tank, a gauge at a distance of 15 ft. from the pipe connected to, registered a pressure of 160 lb. per sq. in., the 1:1 grout over the top of the arch having been in place less than 4 hours.

In stretches of tunnel where dry packing was used above the arch continuously for several hundred feet, cut-off walls were built at intervals of from 75 to 100 ft. to avoid the flow of grout for very long distances, and to prevent the separation of the sand and the cement. Brick cut-off walls were built in connection with the grouting of the wet stretch on the incline north of Shaft 4, Rondout Tunnel. The grouting of this stretch is described in detail later.

Drip-Pans vs. Deep-Seated Pipes.—There may be a difference of opinion as to the best method of treatment in taking care of incoming water and subsequent grouting where the leakage into the tunnel extends over a considerable area. Although in numerous cases deep holes were drilled into the water-bearing seams to collect the water, it was not the general practice to drill an extensive number of such holes where large wet areas were encountered. The use of drip-pans, whereby all the open seams are exposed directly to the action of the grout, is believed to be the best method of treatment in such cases. In either method, penetration of the grout is probably very slight in the case of small openings in the rock.

In two cases where excessively wet stretches of tunnel were encountered, namely, in Rondout Tunnel, north of Shaft 4, and in the City Aqueduct Tunnel, near Shaft 24, light steel shells consisting of ribs and plates were used to protect the concrete during placing. (See Fig. 5.)

The space between the shell and the rock was dry packed and subsequently grouted. In addition, holes were drilled directly into the seams and grouted. Very successful results were obtained by the methods adopted in these two stretches. There were other places where deep holes were drilled in wet ground and grout forced in the rock with very good results. Where conditions are favorable, that is, in porous and broken-up rock with open and distinct seams, permitting the free circulation of the grout, deep-seated pipes are undoubtedly very effective in grouting the rock. A sufficient number of deep holes should be drilled, however, so as to intersect as many seams as possible.

For a short distance south of Shaft 14 in the City Tunnel, practically the whole face of the rock was dripping water. To avoid covering the entire area with drip-pans, parallel strips of pans, about 2 ft. wide and a few feet apart, were placed around the upper half of the tunnel. It was thought that the water would find less resistance in traveling through a few feet of fissured rock than through the newly placed concrete lining. This proved to be the case, as all the water came through the grout pipes connected with the pans. Through these same pipes the tunnel was grouted very successfully.

To test the efficacy of the grouting of the rock by means of deep-seated pipes, test holes were drilled through the concrete lining in the Rondout Tunnel and into the rock in the very wet stretch. With one exception, the holes showed a slight seepage, indicating that the grout had filled the water-bearing seams adjacent to the tunnel. In one hole, however, drilled about 8 ft. into the rock in the invert, a flow of 71 gal. per min. was struck, although 133 bags of cement had been forced into a hole about 5 ft. away during the original high-pressure grouting. This test shows that the character of the rock, the nature and size of the openings, and other conditions must be carefully studied in locating the holes for grouting. Another requisite for success in grouting the deep-seated pipes is the use of thin grout. It is also important to inject the grout continuously, so that the ground-water pressure will not force it back into the pipe or hole.

Deep holes drilled into very fine seams will ordinarily clog the seam with drill chips, making it impossible to force much grout into such seams. Experience showed that not more than one pipe in ten would permit the grouting of fine seams. Deep holes are preferable to shallow holes, as the former are more apt to intersect water-bearing seams and

take more grout. If deep-seated pipes are used along a large water-bearing seam. they should be placed generally not more than 15 ft. apart; the seams where exposed should be raked out to clear them of loose chips of rock, and the edges should be caulked with oakum or covered by a drip-pan before placing the concrete. The difficulty of adjusting the consistency of the grout, where large and small seams occur, has been referred to. Wide seams require thick grout, while fine seams are at once blocked without filling, unless the thinnest grout is used.

Time of Grouting.—The question of the time to be allowed between the placing of the concrete lining and the application of high-pressure grout was given careful consideration, particularly where the tank grouting pressure might be transmitted over a considerable area. It was stipulated in the specifications that grouting under pressure would not generally be ordered in any place until three months after placing the concrete lining at that place. This rule was generally followed, although there were cases where grouting under 300 lb. pressure was done within a month after the placing of the concrete without injury to the lining. There were two or three cases where the lining ruptured at the time of grouting, but the breaks were not due to the lack of age of the concrete. No case of cracking occurred in the top of the arch.

Other considerations controlling the time of grouting are the shrinkage and the imperviousness of the concrete. Tests show that, at the age of 1 month, concrete has developed 80% of its 3 months' strength and has acquired the greater part of its imperviousness. Shrinkage also appears to be complete in from 3 to 4 weeks. It would seem, therefore, that grouting under ordinary conditions can safely be done one month after the placing of the concrete lining.

Cracks in the Concrete Lining.—Reference has been made to the opening of the transverse joints between adjacent sections of the arch and side-walls, due to the contraction of the concrete. Irregular transverse shrinkage cracks also developed between the construction joints, even in the 30 and 40-ft. lengths of arch and side-wall. The cracks were mostly in the arch, but were quite common also in the side-wall. This cracking is due to the contraction of the concrete in cooling from a temperature of 100 to 160° Fahr. during setting, to the normal temperature in the tunnel which in summer was not much above 60° and in the winter sometimes fell below 32° Fahr. near a shaft.

The frequency of the intermediate cracks in the lining was affected by the time of year the concrete was placed. In the City Tunnel, for example, it was found that there were more cracks in the concrete placed during the warm summer months than in that placed during the winter. The richness of the concrete also may have influenced the cracking. There was some inward leakage through the intermediate cracks in the lining after the grouting in the tunnel was completed and the ground-water pressure had accumulated. Most of these leaks, however, silted up after some interval.

There were only two cases where the lining cracked during the high-pressure grouting. In the Moodna Tunnel, several breaks developed in one stretch in the side-wall concrete, the cracks extending in places into the invert concrete. Examination showed that the breaks in this stretch resulted from defective work in connection with the placing of the concrete lining, the defects being due principally to inadequate measures for taking care of the inflowing water which accumulated behind the forms, resulting in the formation of laitance and weakening of the concrete. In grouting the Hudson Tunnel, several cracks developed in the lining under a grouting pressure of 600 lb. per sq. in. On cutting out the concrete at one of the cracks, where a large drip-pan had been used, it was found that a soft deposit had formed between the pan and the rock, so that it had been impossible to fill this space effectively with grout.

Leakage Through Construction Joints.—In wet stretches some difficulty was experienced in cutting off the leakage of water into the tunnel through the transverse joints in the arch. These joints opened up, due to the contraction of the concrete caused by the drop in temperature from the time of setting to the time of grouting. Holes drilled into the joints through the concrete and grouted proved ineffective, as the running water would wash out the grout.

Various schemes were tried to make the transverse joints tight, among which were the following: Grouting grooves were formed at the end of each arch section, either by embedding a slit rubber hose in the concrete or by nailing a strip of sheet iron over a recess left in it at the joint. These grooves were grouted through pipes set in the concrete. The results were not entirely successful in cutting off the leakage. Better results were obtained by the use of steel plates embedded in the arch joints, the purpose of the plates being to provide a

water-stop as well as to retain the grout. These schemes were used only to a very limited extent at the beginning of the work, and, later, were abandoned.

Very good results were obtained in closing wet transverse joints by hand-caulking them. Grooves about 1½ in. deep were cut along the joint and ¼-in. lead wire was hammered in. This method proved quite effective in making the joints tight.

The longitudinal joints between the invert and side-walls were found to be tight. At the joint between the side-walls and the arch some leakage occurred in the wet places. There was also some inward leakage in places at the longitudinal joints in the arch. The greater part of this leakage was due to porous concrete in the vicinity of the joint, where a relatively dry concrete had to be used, and part may have been the result of a slight opening of the joints due to the lateral contraction of the concrete.

Inspection of Grout in Place.—In order to see how effective the grout was in filling void spaces back of the concrete lining, test holes were cut in the arch concrete in several places in the pressure tunnels. Blocks of concrete about 1 ft. square were cut out in the arch, exposing the rock in the roof. It was found that the space between the top of the arch concrete and the rock was well filled with grout, and tests showed the grout filling to be dense and hard. As a somewhat dry consistency is used for the concrete in the top of the arch, this concrete when placed is likely to be porous in places; in the concrete cut out of the test holes, the grout was found to fill the voids in this concrete, and the entire block was a dense and uniform mass that was in solid contact with the rock. Test holes were also cut from the lining in the Rondout Pressure Tunnel where grout was used to fill the shrinkage space at the top of the concrete lining placed inside of a steel reinforcing shell. Here, also, excellent filling was found between the concrete and the steel.

Several opportunities were also afforded to observe the results of the grouting during the progress of the work. In grouting the wet seam in the Hudson River Tunnel near the East Shaft, already referred to, the seam, as stated, was found to be well filled with grout when exposed by the excavation. In sinking the wet shaft, known as Shaft 4, at the Rondout Pressure Tunnel, grouting was resorted to, as the shaft was deepened to cut off the inward leakage, and the sub-

sequent excavation through the grouted zone showed the seams in the rock well filled with grout. The grouting in this shaft is described subsequently in more detail.

In Shafts 22 and 24 of the City Tunnel, where the wet portions were grouted as the shafts were sunk, subsequent excavation showed that all but the very fine seams were completely filled with grout.

Reduction of Inward Leakage After Grouting.—An idea of the effectiveness of the concrete lining and the grouting in cutting off leakage into the pressure tunnels is given by the data in Table 2.

TABLE 2.—LEAKAGE INTO PRESSURE TUNNELS.

Pressure Tunnel.	Length, in feet.	LEAKAGE INTO TUNNEL, IN GALLONS PER MINUTE.	
		Before grouting.	After grouting.
Rondout, wet stretch north of Shaft 4	350	850	3
Rondout (exclusive of above wet stretch)	23 610	200	49
Wallkill	23 390	506	75
Moodna	24 100	496	85
City, wet stretch near Shaft 23	90	325	8
City (exclusive of above wet stretch)	93 810	973	127

Hydrostatic Tests of Pressure Tunnels.—After the pressure tunnels and shafts were completed, they were filled with water in order to test their tightness. The tests in some cases were unusually severe, as the full ground-water head had not been restored at the time the test was made. At the Rondout Pressure Tunnel, the maximum unbalanced head at the beginning of the first hydrostatic test was approximately 500 ft. After the tests, the tunnels were unwatered for inspection and repairs, and the results were found to be very satisfactory, the tunnels proving remarkably tight.

Only in four places, in the 35 miles of pressure tunnel, aggregating in length about 2 500 ft., did any weakness develop, due to the yielding of the surrounding rock, causing rupture of the lining and outward leakage and making subsequent repairs necessary. In these cases, it would have been impossible to reveal fully in advance the geological conditions, particularly where the rock appeared to be sound when the tunnel was excavated, and it is believed that no amount of grouting prior to the application of the test pressure would have been adequate to consolidate the ground sufficiently to prevent the yielding of the rock. The cost of testing the tunnels and making the necessary

repairs was very much less than it would have been to make the tunnels absolutely secure by the use of steel reinforcement in the concrete lining for their entire length.

Equipment for Grouting.

Air-Stirring Grout Tanks.—Tank grouting machines of the Canniff type were used almost exclusively for grouting. These machines are very simple in construction and operation, consisting essentially of a tight cylinder provided with suitable pipe connections for introducing compressed air and for mixing and ejecting the grout. The tanks are very compact, weigh about 500 lb. when empty, and have no moving parts to wear out and be replaced. They are, therefore, particularly well suited for tunnel work. Both thick and thin mixtures can be used in them, and they are equally well adapted for high and low-pressure work. They are very efficient where large quantities of grout have to be placed.

A slight disadvantage of the Canniff tank is found when grouting fine seams under high pressure, or placing small quantities of 1:1 grout. As the process is necessarily slow there is a tendency for the cement, but more particularly the sand, to settle in the bottom of the tank and clog the openings. The use of very thin grout usually overcomes the difficulty.

As a rule, two grouting tanks were operated simultaneously in grouting the tunnel, one being charged while the other was discharging. For high-pressure work, however, it was the usual practice to use only one tank. The two tanks were mounted either alone on a low flat car, or at one end of a platform car which was large enough to hold, in addition, from 20 to 30 bags of sand and cement. In some cases, an upper platform was also provided for materials. The materials were hauled through the tunnel by mules or motor trucks. The water for mixing was measured either by pails, or automatically by a tank placed at the side or above the grout tanks. High-pressure armored hose about 25 ft. long was used for grouting purposes. The plant used for grouting on the work at the lower end of the City Tunnel is shown in Fig. 6.

Operation of Grout Tanks.—The usual method of operation during low-pressure grouting, was first to put into the tank the required quantity of water, then to let the air into the tank at the bottom.

which agitated the water, and then the cement and sand were put into the tank and stirred by hand with a wooden paddle, as it was found that the air was too slow for mixing and was also wasteful. When thoroughly mixed, the door at the top of the tank was closed, the air was then admitted at the top, and the liquid grout forced out through the grout hose into the pipe connected to. The air was then turned off quickly.

Unless care is taken to close the air discharge valve the instant the last of the grout leaves the tank, an after-blast of air follows the grout, resulting in stirring it up and causing separation of the materials, and also tending to form air pockets in the space grouted. The men operating the tanks, however, soon became skilled in controlling the discharge. As an added precaution, the air-pressure gauge on the grout tank was watched closely to note the fall of pressure as the grout discharged, and the emptying of the tank was also indicated by the "kick" of the grout hose when the charge left it.

In some cases the following scheme was tried. The air valve was closed as the batch of grout started to leave the tank, permitting the air in the tank to expand and force the grout through the hose. This method, however, was slow and was not generally used. Where the grout displaced water, the ejection of the grout by expanding the air in the tank was quite effective in cutting down the after-blast of air. The tanks could be operated very rapidly. As much as 1 500 batches of 1:1 grout, equivalent to about 115 cu. yd., were placed in 24 hours, using two tanks. This process involved the handling of about 135 tons of cement and sand in the 24 hours.

High-Pressure Air Compressors.—The air for operating the grout tanks was obtained by connecting to the air line laid in the tunnel, the air pressure in the line being usually from 80 to 100 lb. In order to provide the pressures required for high-pressure grouting, small Westinghouse direct-acting single-stage air compressors, known as "boosters", were generally used. These compressors, mounted on the same car with the grout tanks, took suction from the main air line and delivered air in the tanks at a pressure of 300 lb. per sq. in. The compressors weigh about 500 lb. They are provided with air gauges registering up to 450 lb. per sq. in. A spring relief valve, capable of being set at any pressure up to 400 lb., is placed on the main discharge. Each branch of the 2-way discharge is supplied with a stop valve, a

check valve, and air emergency stop valve, so that it may be closed automatically by a sudden release of pressure due to the bursting of hose or any other reason.

Independent Air-Generating Plant in Tunnel.—The grouting in the tunnel necessitated the maintenance and operation of the large compressor plant used for tunnel driving and the re-laying of the air pipe line in the tunnel, which had been taken up during the placing of the lining. In order to avoid the use of the expensive main air plant some of the contractors used small independent portable compressors in the tunnel, driven by gasoline or electricity, and mounted on cars traveling along with the other equipment. These compressors were used both for the low and high-pressure grouting.

On the work in the northern portion of the City Tunnel, low-pressure grouting was carried on with three rigs, each consisting of the following equipment: One 30-h. p. electric motor; one Ingersoll-Rand 2-stage, belt-driven air compressor, capable of delivering 170 cu. ft. of free air per min. at 100 lb. pressure and 130 cu. ft. at 350 lb.; one geared pump, with a capacity of 50 gal. per min., driven by a 7½-h. p. electric motor; two grout tanks, two water tanks, a platform car for making connections to the grout pipes, and a platform mounted on two flat cars for the cement and sand. For high-pressure grouting the same rig was used, the compressor being adjusted to deliver air at 300 lb. per sq. in.

Grouting by Air and Water Pump.—In the Hudson Tunnel, where it was necessary to use grouting pressures of 700 lb. per sq. in., a combination of air and water-pressure pump was devised. A Canniff tank was partly filled with grout which was placed under a pressure of about 300 lb. by a Westinghouse booster connected as usual with the tank. Water was then pumped into the tank through another connection by a high-pressure Cameron pump, reducing the volume of air above the grout so as to raise the pressure to 700 lb. per sq. in., if desired. The discharge valve of the tank was then opened, and the pump was kept going in order to maintain the pressure while the grout flowed slowly into the space back of the lining. This arrangement worked very successfully. The advantage of a pump with a steady flow lies in the fact that there is no after-blast of air forced through the grout.

Paddle Mixing Machines.—In a few cases, paddle mixing machines which mix the grout mechanically instead of by air, were used. The results obtained by these machines are good when they are new, but the moving parts and the stuffing boxes soon give trouble on account of wear. The bad feature of both the air-stirring grout tanks and the paddle mixing machines is the blast of air which follows the discharge of grout. As already noted, it is very important to control the discharge of air in grouting in order to secure good results.

Grouting Pads.—The specifications called for the use of grouting pads for forcing grout into any porous concrete in the lining. These pads consisted of a steel casting measuring about 1 ft. by 2 ft. 3 in., containing a rubber gasket, and mounted at the end of a 5-in. extra heavy wrought-iron pipe. In using the grout pad, it was jacked against the porous spot in the lining by screw-jacks at the other end of the column, and the grout was then forced into the pad to impregnate the concrete. These pads were not successful, as they were clumsy to handle, the area covered by the pad was too small for effective work, and the gaskets would blow out. After a few attempts, their use was given up.

Only a few porous spots occurred in the concrete lining through which grout leaked during low-pressure grouting, and it was found that the most effective method of treatment was to wedge a board faced with oakum against the porous spot. The flow of grout soon stopped and the opening closed up.

Special Grouting in Pressure Tunnels.

Grouting Wet Stretch, Rondout Tunnel.—This pressure tunnel, 4.4 miles long, was constructed from eight shafts, varying in depth from 370 to 708 ft. The shafts and tunnel penetrated eight distinct formations, including shales, limestones, and quartz conglomerate. Several stretches of faulted zones and crushed rock were encountered in the excavation. Some strata were dry; others were very porous and water-bearing.

As already described, the tunnel north of Shaft 4 was driven on a 15% grade through a badly faulted and folded stretch in High Falls shale and Binnewater sandstone. The rock was porous and water-bearing, the inflow in a stretch of 350 ft. being approximately 2 000 gal. per min. at the time the tunnel was driven. The flow gradually

diminished until it was somewhat less than 1 000 gal. per min. at the time the lining was placed. The tunnel at this location is about 450 ft. below the surface of the ground. An attempt to shut off the inflowing water by grouting at the time of driving has been described.

It would have been difficult to take care of the water by means of drip-pans during the placing of the lining, as it poured into the tunnel over large areas. The plan adopted to protect the concrete during placing was to enlarge the excavation through the wet stretch in order to permit the erection of a light steel shell (see Fig. 5), inside of which a concrete lining, 24 in. thick, was placed. The shell was 175 ft. long, and consisted of circular ribs of 7-in., I-beams set 5 ft. center to center along the tunnel, with $\frac{3}{16}$-in. plates bolted to the outside of the ribs. The space between the shell and the rock, which averaged about 20 in., was packed solid with broken stone and subsequently grouted.

Most of the water entering the tunnel in this stretch was intercepted by 6-in. lateral pipes draining into an 8-in., spiral-riveted drain laid longitudinally along the bottom of the tunnel. This drain discharged through an 8-in. valve into a sump at the foot of the wet stretch. Water was also collected through holes drilled into the rock seams to depths of from 3 to 4 ft., into which 2-in. deep-seated pipes were set, which extended through the dry packing and the steel shell and drained into the tunnel. Pipes were also placed through holes in the shell to reach the dry-packed space for the purpose of grouting the packing behind the shell.

The concrete invert, which averaged about 3 ft. in thickness, was laid first on the floor of the tunnel over the 8-in. drain. The invert was placed in short stretches, 25 and 40 ft. in length, with tight wooden bulkheads and forms. Any leakage in the bottom was taken care of by pans and broken stone drains covered with cement bags. The placing of the invert was very difficult on account of the heavy flow of water from the bottom and sides of the tunnel. After the invert was placed, the steel shell was erected and the space between the shell and the rock was dry packed at the same time. The lining was then placed inside the shell without any trouble.

Preliminary to grouting this stretch, tight brick cut-off walls were built between the shell and the roof at each end of the shell. When grouting was started, the valve at the lower end of the 8-in. drain was

closed and the valves of all the pipes leading into the dry packing were also closed. The dry-packed space was quickly filled, forming a pond of still water, into which neat cement grout was injected. Experiments previously made showed that the materials in sand grout might separate if forced in under water. The deep-seated pipes and a few pipes at the top of the shell were left open to prevent accumulation of pressure.

Grouting of the dry packing was begun at the lower end of the shell. A battery of four Canniff grout tanks was used, the grouting of both sides of the tunnel being carried on simultaneously. The space behind the shell filled gradually, the level of the grout being indicated by opening pipes at various levels. A few of the deep-seated pipes flowed grout during this operation. They were closed, but were re-opened about 24 hours later and rodded out, after which they again flowed clear water, but in a somewhat diminished volume. In the whole section the inward leakage was reduced from 850 to 540 gal. per min. after grouting the dry packing, showing that the seams had been partly closed. The grout was injected into the dry-packed space, generally under low pressure, without causing undue agitation. The final grouting was done under a pressure of 90 lb. per sq. in. at the top of the shell. A total of 7 700 batches of neat grout (1.2 cu. ft. per batch) was forced into the dry packing, requiring ten shifts.

After the grout had set a few days, the deep-seated pipes through which several hundred gallons of water per minute issued into the tunnel, were grouted, beginning at the bottom of the shell and working up. During this process, varying consistencies of grout were used, the thinnest being ¼ bag of cement (about 24 lb.) to 30 gal. of water. After applying air pressure to clean out a rock seam, the thinnest grout was used first. If a considerable quantity, 20 to 30 batches, went into the rock under comparatively low pressure (100 lb., or less), the grout was thickened, 48 lb. to 30 gal. of water being used. If a considerable quantity of this grout was injected, the mix was again thickened, this process being continued until the tank pressure necessary for injection began to rise, when the mix was thinned slightly, and grouting continued until the pipe refused under 300 lb. pressure. The pipe was then drained out and plugged with thick neat cement grout under 300 lb. pressure. The maximum number of batches injected into a pipe was 533.

The grouting reduced the leakage on the incline from 850 to 3 gal. per min., and although the level of the water in the rock reservoir, as indicated by gauge readings, rose gradually after the completion of the grouting until the original ground-water level had been restored, there was no marked increase in the quantity of water entering the tunnel. Test holes drilled through the concrete lining and shell and into the rock showed that the rock surrounding the tunnel was impregnated with grout to a considerable depth. The success of the grouting at this location was due to the use of the deep-seated pipes, and, more particularly, to the method adopted whereby the dry-packed section outside of the lining and shell permitted the grout to come in direct contact with the surface of the porous rock.

Grouting Large Mud Seams, Rondout Tunnel.—In driving the tunnel through the Helderberg limestone south of Shaft 3, Rondout Tunnel, a crushed and faulted zone containing a number of large solution cavities filled with residual clay was encountered. The two widest seams were vertical and cut diagonally across the tunnel at an angle of about 45° to the tunnel axis. These two seams were 16 and 25 ft. wide on one side of the tunnel, but much narrower on the other side. They were filled with clay and disintegrated rock and, while excavating the tunnel, were lagged with steel channels supported by steel beams and timbering. The lining at the seams was strengthened by embedding steel shells, ½ in. thick and 41 and 59 ft. in length, in the concrete at each seam. In addition to reinforcing the lining, these shells also serve to prevent outward leakage from the tunnel.

In this stretch, a horizontal seam about 3 ft. thick also was encountered, the bottom of the seam lying about 4 ft. above the finished waterway. The mud layer was removed and the space above the waterway, about 7 ft. high, was subsequently filled with concrete. Above the horizontal mud seam was an opening in which were three rows of narrow vertical pockets, extending diagonally across the tunnel. These pockets were from 2 to 6 ft. wide and ran from a few feet to 30 ft. above the roof of the tunnel. Concrete was placed up to the top of the general roof excavation and the space above, including the narrow pockets, was filled with grout through pipes set in the concrete. A total of approximately 9 000 batches of 1:1 grout was placed in this stretch, requiring 13 days of three shifts each.

Rupture of Lining and Repair Work, Rondout Tunnel.—On the completion of the tunnel and shafts, they were filled with water for a hydrostatic test. Excessive leakage developed in the Rondout Tunnel and, after unwatering it, an examination showed that the lining was cracked in three stretches aggregating in length about 700 ft. The upper half of the tunnel section appeared to be lifted from the lower portion, water issuing in large quantities through the joint at the springing line and through other diagonal cracks in the lining.

To determine whether the lining had ruptured on account of unfilled places over the top of the arch, a test hole was cut, and several holes were drilled through the concrete to the rock in the roof. The space was found to be completely filled with grout, which was intact and in close contact with the rock. The rupture of the lining was due to the movement of the rock outside of the tunnel resulting from the application of hydrostatic pressure.

The tunnel was reinforced through the ruptured stretches by steel lining built up of rings of circular segments of 15-in., 55-lb. channels. A 2-in. annular space was left between the steel and the existing concrete lining. Preparatory to placing the steel, the cracks through which water issued were caulked with lead, thereby forcing the water into pipes drilled through the lining into the rock seams.

The space between the steel shell and the old concrete lining was first grouted. Every twelfth ring of steel had eight holes placed equally around the circumference, tapped and plugged for grouting. A 1:1 grout was used under a pressure of 30 lb. per sq. in. After this grout had set for one week, the deep-seated pipes leading to the wet seams were grouted. Very thin grout, ¼ bag to 35 gal. of water, was forced in until the hole refused at 300 lb. pressure. The thin grout was then drained out of the pipe, which was sealed with a thick batch. A total of 743 bags of cement was injected through 89 pipes. The leakage in this section before repairs were started amounted to about 400 gal. per min. After all the concrete was placed and all the grouting was finally completed, it was reduced to 2 gal. per min.

To protect the steel shell against rusting, and to provide a smooth waterway, a concrete lining, averaging 6 in. in thickness, was placed inside the steel shell. To fill the space above the arch, a grout and a vent pipe were placed in each pocket formed by the projecting flanges of the channels. A thick 1:1 mixture was used for the grouting, the

grout being placed by a Douglas hand pump. After this grout had set, and the surplus water was allowed to drain off, a second grouting was done with neat cement, completely filling the space between the lining and the steel shell.

Wallkill Pressure Tunnel.—This tunnel crosses the Wallkill Valley for a distance of 4½ miles, at an average depth below the ground surface of 350 to 450 ft. The rock penetrated was the Hudson River shale formation, and was generally sound and dry. For the greater length, the rock was a rather fine-grained shale with some beds of hard sandstone; for about a mile at the south end of the tunnel, it was mainly sandstone in very heavy beds. The dip of the rock for the greater length of the tunnel averaged about 45°, striking at an angle of about 30° with the tunnel line. At the north end, the bedding was vertical and at right angles with the tunnel axis; while for a considerable distance at the south end the beds were horizontal, causing high breakage above the roof.

The inward leakage when the tunnel was driven amounted to approximately 500 gal. per min. in the tunnel and 180 gal. per min. from the shafts. Although no great concentrated flows of water were met, certain stretches were water-bearing over large areas and the rock was extensively covered by pans to catch the water. Eight stretches of 1 000 ft. in length yielded an inward flow of more than 20 gal. per min. before grouting. The maximum inward leakage of ground-water was 90 gal. per min. for 1 000 ft. of tunnel.

In many places the water entered in fine sheets under head between the layers of shale. It was found to be practically impossible to force any quantity of grout into this rock on account of the fine openings between the thin layers. The wet areas were covered by drip-pans and grouted under high pressure with neat cement grout by filling the pans solidly full, sealing the fine openings, and effectively cutting off the water.

An interesting movement of the flow of water in the rock during grouting occurred between Shafts 1 and 2. The total leakage in this stretch just prior to starting grouting was 125 gal. per min. There was little diminution in the leakage after the low-pressure grouting and it was not until the high-pressure grouting plant had traveled a distance of about 3 000 ft. south from Shaft 1 to within about 2 000 ft. of Shaft 2, that any marked change in the inflow occurred. In

FIG. 7.—BROKEN TUNNEL LINING, RONDOUT PRESSURE TUNNEL. CRACKS DUE TO YIELDING OF ROCK. LEAKAGE REDUCED FROM 400 TO 2 GAL. PER MIN. BY GROUTING.

FIG. 8.—STEEL INTERLINING THROUGH DECOMPOSED ROCK, CITY TUNNEL, UNDER 106TH STREET. SPACE BACK OF LINING CONSOLIDATED BY GROUTING.

two days of grouting, the leakage in this stretch dropped to 70 gal. per min.

Evidently, the water in a length of 3 000 ft. of tunnel, south of Shaft 1, was forced ahead during the high-pressure grouting, finding an outlet through grout pipes in the arch south of the grouting machine. There was a soft seam or plane of movement above the roof of the tunnel in this stretch, running nearly parallel with the tunnel, and apparently the water was forced through this seam during the grouting. On the completion of the grouting, the leakage in this stretch was reduced to 22 gal. per min.

Moodna Pressure Tunnel.—This tunnel is 4.8 miles long, and from 300 to 400 ft. below the surface of the ground, the maximum depth below the hydraulic gradient being about 600 ft. The tunnel penetrated Hudson River shale for about 60% of the distance and granitic gneiss for the remainder of the length. The shale was generally soft, although there were many layers of hard sandstone; the rock was much disturbed and without uniformity of attitude. The gneiss was hard and sound, but intersected in every direction by joint planes as a result of the disturbance due to a great overthrust fault which extends for many miles along the contact between the gneiss and the Hudson River shale formations.

The inward leakage for the entire tunnel, including the shafts, was 640 gal. per min. when the excavation was completed. The shale was wetter than the gneiss, but there were no large concentrated flows anywhere. Very few holes were drilled for deep-seated pipes, as practically no well defined water-bearing seams were encountered. In the shale, a drip-pan was placed about every 7 or 8 ft. of tunnel.

The rock throughout was generally firm and only 3% of the length of the tunnel required roof support. Although several zones of extensive rock movement were penetrated, there were no large openings or excessive inflows at these places, and special treatment was required in only one case, where badly crushed and unstable ground was encountered beneath the surface valley known as Pagenstecher Gorge.

In this stretch, a flow of about 100 gal. per min. was struck when the heading was first excavated. The water issued from a crevice 6 in. wide, marking a plane of movement and solution in the gneiss. The adjacent rock was crushed and disintegrated, and required a

steel roof support for a distance of 55 ft. along the tunnel. Following the first rush of water from the crevice, the leakage gradually diminished, as the underground storage was exhausted, until it was less than 10 gal. per min.

The rock broke very high and wide at this place, and, in making arrangements for grouting, long grout pipes were set to reach the top and sides of the cavity. The longest pipe extended 20 ft. above the roof of the tunnel. The dry packing between the steel support and the rock was first grouted, the operation being continued until the water-bearing crevice was filled. After the grout had settled and set, the long pipes were opened up and drained, and any remaining spaces were filled with grout under a pressure of 300 lb. per sq. in.

Repair Work in Moodna Pressure Tunnel.—The Moodna Tunnel connects at the south end with the tunnel under the Hudson River by a shaft on the west bank. Although the rock in Moodna Tunnel adjacent to the West Shaft was dense and solid when excavated, the application of hydrostatic pressure, when the tunnel was tested, caused a movement along the joint planes, with rupture of the concrete lining both in the West Shaft and in a stretch of Moodna Tunnel adjacent to the shaft. As the joint planes in the rock were closed and tight before the test pressure was applied, it would have been impossible to prevent the yielding of the rock by grouting, no matter how thorough and extensive, prior to the hydrostatic test. The cracks in the lining through which considerable water issued were subsequently caulked, and the rock was grouted. Later, it was decided, on account of the geological conditions which the test had revealed, to abandon 900 ft. of the tunnel adjacent to the West Shaft, and a new tunnel was driven 400 ft. below the old one. No further trouble was experienced at this location.

Hudson Pressure Tunnel.—This tunnel, placed 1 100 ft. below the river surface, penetrated sound Storm King granite throughout its entire length of 3 100 ft. Numerous black diabase dikes were found along the joint planes. The granite has shared with the entire Highland area in folding and faulting movements which broke up the rock into blocks separated by joint planes. In excavating the tunnel, some water from the river entered through this system of joints.

The grouting of a wet seam near the East Shaft in driving the tunnel has been described. Contrary to expectations, the leakage of

water into the tunnel was not excessive, and was taken care of in the usual manner by the use of drip-pans and deep-seated pipes. The total inward leakage after the completion of the concrete lining and prior to grouting was 160 gal. per min., the greater part occurring near the western portion of the tunnel.

As already described, some trouble was experienced in this tunnel on account of the cracking of the concrete lining in the side-walls, when the high grouting pressures, running up to 600 lb. per sq. in., were applied. After the cracks were cut out, the lining was replaced and again grouted under lower pressure, and no further trouble developed. As noted, a soft deposit was found between one of the drip-pans and the rock at one of the cracks which had been cut out, which probably prevented the filling of the space with grout. Several unusually large drip-pans were used in the wet stretches, and this may have been a factor in the cracking of the lining, as the very high grouting pressures were applied over large areas where the lining was not very thick.

No attempt was made to shut off all inflowing water in this tunnel by grouting, and the pipes which flowed water were fitted with bronze check-valves. These valves prevent the accumulation of rock-water pressure on the lining, when the tunnel is empty, by permitting the water to flow freely into the tunnel, and also, by closing tightly, prevent the loss of water from the tunnel when in service.

The high pressures necessary for grouting this tunnel were obtained by the use of a high-pressure pump which discharged the grout in the grout tank by pumping water into the tank. This tunnel proved to be remarkably tight when tested, and the loss of water when in service is very little.

Repairs in Breakneck Pressure Tunnel.—This tunnel, 780 ft. long, extends from the East Shaft of the Hudson Tunnel to an uptake shaft on the north slope of Breakneck Mountain. It penetrated the same granite formation as the Hudson Tunnel, and the rock was sound and dry. In the portion adjacent to the East Shaft, where the rock cover is comparatively shallow, cracks developed in the tunnel lining, as well as in the upper portion of the East Shaft, when a hydrostatic test was made, due to yielding of the rock along the joint planes. The lining was repaired by drilling holes about 10 ft. deep through the concrete and into the rock, and injecting thin

grout under pressure. Most of the holes took little grout, but there were a few into which a considerable quantity was forced.

The grout was mixed in the proportions of 25 lb. of cement to 20 gal. of water, and, in some cases, even thinner. Water was used for washing out the seams and frequently permitted further grouting after a hole appeared to be plugged. One hole, in the vicinity of a fractured zone in the rock, took 5 217 batches of grout containing 328 bbl. of cement. This hole was almost plugged several times, but was opened by flushing with water.

During grouting, the grout did not appear in any of the other holes in the vicinity of the pipe grouted, but was evidently forced some distance from the tunnel. Only four holes took more than 25 bbl. of cement. A total of 556 bbl. of cement was used in grouting the tunnel and 39 bbl. in the East Shaft. The repairs were successful in reducing the outward leakage to a small quantity.

City Pressure Tunnel.—The City Tunnel forms the great distribution main within the city limits. It is 18 miles long, and is located beneath the streets and parks of the Boroughs of The Bronx and Manhattan, extending from the Hill View Reservoir, just north of the city line, to two terminal shafts in Brooklyn. The tunnel was constructed from 24 shafts, varying in depth from 218 to 757 ft.

The tunnel was placed everywhere at a depth of not less than 150 ft. below the surface of sound rock. The rock is at or near the surface over the greater part of the line, and more than half of the length of the tunnel is little more than 200 ft. below the surface of the ground. In order to secure the required depth of sound rock cover over the tunnel under the Harlem and East Rivers, the tunnel was placed 330 and 700 ft., respectively, below the surface.

The formations penetrated in the City Tunnel, namely, Yonkers and Fordham gneiss, Inwood limestone, Manhattan schist and Ravenswood diorite, are generally sound and durable rocks, but were found in many places to be disturbed by folding and faulting, with extensive crushed zones. Intrusions of pegmatite were frequently met. The underground waters circulating through channels formed by mechanical fracture and solution have caused chemical changes in many stretches, with resulting alteration and weakening of the mineral constituents of the rock. For the greater part of its length, the

tunnel was driven approximately parallel with the strike of the rock, the dip being generally nearly vertical.

With the exception of two or three stretches, where heavy flows of water were encountered, the rock throughout the length of the tunnel was generally dry, and seeping water was taken care of by the methods used in the other tunnels. On account of the location of the City Tunnel, in the heart of the city, unusual precautions were taken in handling the water and grouting, in order to reduce, as far as practicable, the loss of water out of the tunnel, as it was evident that excessive leakage would be exceedingly troublesome and might result in the settlement of buildings.

Grouting under Harlem River, City Tunnel.—The tunnel under the Harlem River Valley penetrated Inwood limestone, a white crystalline marble, solid and dry for the greater part, but, for a distance of about 200 ft., a blocky stretch with water-bearing seams was encountered, yielding a flow of about 200 gal. per min. A number of large crevices, several inches wide, extended above the roof and from the sides of the tunnel. Grout pipes, some 20 ft. long, were inserted in these crevices.

All the leaks in the sides and roof of the tunnel were panned, while, in the bottom, where considerable water issued, a broken stone drain covered by pans was laid below the invert concrete. The inflowing water was drained by a longitudinal pipe on the bottom. During the placing of the invert concrete, the water was kept below the top of the stone drain by pumping through the longitudinal pipe and pumping was continued until the concrete had set.

The grouting in those portions of the tunnel adjacent to the wet stretch was completed before any leakage in that stretch was cut off. Grout was first forced into the bottom drains and pans, the upper pipes being left open to relieve the water pressure. Connections were made successively to the pipes at higher levels, until the crevices in the roof were filled. The final grouting was done under a pressure of 300 lb. per sq. in., using thick cement grout. The grouting was very successful, the inward leakage in this stretch being reduced to 3 gal. per min.

Grouting the Wet Stretch near Shaft 23, City Tunnel.—The wettest stretch in the City Tunnel was encountered near Shaft 23, where, in a crushed zone in granodiorite, a flow of 600 gal. per min., issuing from one seam, was struck when the excavation was first made. This flow

had diminished to 325 gal. per min. at the time the concrete lining was placed. On account of the large flow, it was decided to use a light steel shell to protect the concrete, instead of the customary drip-pans.

The construction was similar to that in the Rondout Tunnel and consisted of ribs built up of 4 by 3 by ½-in. angles spaced 5 ft. center to center, on which plates ⅜ in. thick were placed. Each rib was made in four segments, the bottom being embedded in the invert concrete. Where the rock showed any leakage, the space between the steel shell and the rock was filled with dry packing, elsewhere the steel plates were omitted, and the concrete lining was placed directly against the rock. Dry packing was placed over about 60% of the area in the 90 ft. of tunnel in which this special construction was used.

The water in the wet stretch was drained by a 10-in. tile pipe, laid with open joints on the floor of the tunnel and surrounded by broken stone. Above the top of the broken stone, corrugated sheet iron was placed, on which the invert concrete was laid. The 10-in. tile drain had a slope of 6 in. in 100 ft. and discharged the water into a sump at the end of the wet stretch. From the sump, the water was pumped into an 8-in. discharge line in the tunnel by a motor-driven centrifugal pump.

After all the other grouting in the tunnel between Shafts 23 and 24 had been completed, that in the wet stretch was begun by first connecting to the pipes in the bottom drain and then successively to the pipes at the higher levels, raising the grout up to a maximum of 150 lb. per sq. in. By this means, most of the grout was placed against a back pressure of 50 lb. per sq. in. or less, the gauge registering finally 90 lb. per sq. in. when the grouting plugged it.

In order to prevent the accumulation of ground-water pressure, all the pipes except those in the invert were left open, or were opened up after the grout had set. After the deep-seated pipes were grouted under a pressure of 300 lb. per sq. in., all the pipes were opened and connected to for high-pressure grouting. A total of 217 batches of neat cement grout, consisting of 1 bag of cement (95 lb.) and 6 gal. of water, was used for the high-pressure grouting in this stretch. Very successful results were obtained in cutting down the inward leakage which was reduced by grouting to 6 gal. per min. for the entire stretch of 3 600 ft. of tunnel between Shafts 23 and 24. Inspection of the tunnel after a

hydrostatic test under the operating head, showed no cracking or inward leakage in this stretch.

Repairs in City Tunnel Between Shafts 18 and 19.—The portion of the City Tunnel underneath Broadway, in the vicinity of 23d Street, was excavated through fairly sound Manhattan schist, with no inward leakage. When the tunnel was subjected to a hydrostatic test, some water appeared at the surface in Madison Square Park and in some of the cellars near-by. Although the outward leakage was not excessive, it was decided to make an effort to cut down the quantity as much as practicable. On unwatering the tunnel, it was found that, due to movement of the surrounding rock, the construction joints of the tunnel lining had opened up and, in addition, some of the lining was cracked. Four stretches of tunnel aggregating 1 350 ft. in length were affected.

The method of repair adopted was to consolidate the rock surrounding the tunnel by grouting and, in addition, to line with sheet copper two stretches aggregating about 1 200 ft. of tunnel. A large number of holes, 2 in. in diameter, were drilled through the concrete lining and into the rock, the size of the tunnel limiting the maximum depth of the holes to 10 ft. In the 1 350 ft. of tunnel grouted, approximately 10 000 lin. ft. of holes were drilled. Pieces of 1½-in. pipe, 15 in. long, were fitted into these holes.

Before grouting, grooves were cut in the joints and cracks through which water entered the tunnel and these joints were caulked with lead wire. The customary grouting equipment was used for this work, air at 90 lb. being furnished by a compressor at the top of the shaft. Higher pressures were obtained by Westinghouse "boosters".

After connecting to a hole, grouting was continued, until the hole refused grout under 300 lb. pressure. Any leaks that developed during the grouting were located, and, after the grout had set, additional holes were drilled at the place of leakage. The process of drilling and grouting a section was continued until test holes, drilled 10 ft. deep, did not leak or take grout. The stretches in which the lining was cracked were grouted three times, a portion of one being grouted five times.

The mix ordinarily used consisted of batches containing 25 lb. of cement to 20 gal. of water. If a hole into which 75 batches of this consistency had been injected, continued to take grout freely, the mix was thickened to 25 lb. of cement and 5 gal. of water; but if the hole showed

a tendency to plug, the thin mix was again used. A total of 6 000 bags of cement were used in grouting the 1 350 ft. of tunnel.

When the grouting was started, the inward leakage amounted to 30 gal. per min., practically all of which was cut off by grouting. The ground-water head against the lining during grouting, as indicated by gauges, was 78 lb. per sq. in. After the tunnel was again placed in service, there was practically no leakage at the surface of the ground.

Grouting in Shafts.

In connection with the construction of the pressure tunnels of the Catskill Aqueduct, fifty-five shafts were sunk. Some of these are permanent, forming part of the waterway; the others were sunk only to expedite the tunnel excavation, and subsequently were closed by concrete plugs. The shafts varied in depth from 106 ft. to a maximum of 1 187 ft., the average being about 400 ft.

As in the case of the tunnels, the shafts penetrated a wide assortment of rock. With a few exceptions, however, no great difficulties were experienced in sinking them, as the rock encountered was generally sound and free from large quantities of water. In some of the shafts where the inflow of water was excessive, the rock seams were grouted during sinking in order to cut off or reduce the flow. In general, the water-bearing ground did not extend to any great depth, but was found in zones about 20 to 30 ft. thick, so that, after the wet portion of the shaft was grouted and passed, no further grouting was necessary in the remainder of the shaft.

Shaft sinking is slow and expensive when large quantities of water have to be handled. The water collects in the bottom, making it troublesome to drill and to muck the broken rock, thereby delaying the work. The maintenance and operation of pumps also interferes with the excavation and increases the cost. The method of grouting water-bearing seams in a shaft during excavation, to cut off the inflowing water, has been used to some extent, although the process has been more fully developed and applied during the last few years.

The method usually adopted in grouting a wet zone is to drill a number of vertical holes in the bottom of the shaft, about 10 to 20 ft. in depth and located generally from 5 to 10 ft. around the periphery of the shaft. Short lengths of pipe fitted with valves are set into the drill holes, and the drilling is done through the valves which can be quickly closed if a heavy flow of water is struck.

After the holes have been drilled, grout is forced into the rock seams through them, by the usual grouting equipment. As in other grouting, a thick grout is best for filling large cavities, while a thin grout, as thin as 5 lb. of cement to 25 gal. of water, is necessary during the early stages of the injection of the grout, in order to make the cement carry as far as possible into the fine seams and avoid the plugging of the seams close to the drill hole. The matter of adjusting the consistency of the grout is important to insure success. After the grout has set up, and the water is cut off, sinking is resumed, using light shots to avoid opening up new fissures in the rock. The method of grouting outlined was used in sinking through wet ground in several of the Catskill shafts. The sinking in these cases would have been much more difficult, slower, and more expensive, had pumping alone been depended on.

Shaft 4, Rondout Pressure Tunnel.—This shaft, 500 ft. deep, was one of the construction shafts for the Rondout Pressure Tunnel. It was rectangular in shape and was timbered as it was sunk. This was the wettest shaft on the Catskill work, and the grouting of the water-bearing strata encountered in its excavation was very successful in cutting down the inflow of water, although pumping had to be carried on continuously during the sinking as additional wet seams were struck. A detailed description of the sinking of this shaft has been given in a paper* by John P. Hogan, M. Am. Soc. C. E.

Preliminary exploration by borings showed that the shaft would penetrate Binnewater sandstone and High Falls shale at a depth of about 200 ft. The rock cores from these beds showed a very porous condition, and pumping experiments indicated that the rocks were freely water-bearing. It is probable that considerable time would have been saved and expensive pumping eliminated during the sinking of the shaft if 4-in. holes had been drilled close together around the perimeter of the shaft when the water-bearing strata were reached, and the rock thoroughly solidified by injecting grout into the seams through these holes. The shaft could then have been excavated in the dry.

However, the drilling of the large holes necessary to insure the complete success of the grouting under such a method would have been a slow and expensive procedure, and experience at the time did not

* "Sinking a Wet Shaft", *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 398.

recommend it as the best method of meeting the situation. The handling of water by pumping was familiar to the shaft sinkers who kept on drilling and mucking until stopped by an excess of water, even though the shaft was flooded several times before the grouting was done.

The shaft was dry until a depth of 215 ft. was reached, when the water-bearing Binnewater sandstone was encountered. At a depth of 260 ft., the flow had increased to 225 gal. per min. While drilling the next round of holes, one of the holes struck such a strong flow that the men had to leave hurriedly, and the shaft was flooded to within 70 ft. of the top. The maximum flow of water entering through the drill holes in the bottom was estimated to be approximately 600 gal. per min.

After a long delay, the shaft was pumped out, and the hole in the bottom was plugged with a 2-in. nipple and gate-valve. Drilling was then resumed in the bottom, through valves on pipes set into the drill holes, the valves being shut as water was encountered. On account of trouble with the pumps and the suction and discharge pipes, the shaft was again flooded twice in succession and each time recovered.

The last holes drilled in the bottom indicated that for the next 8 ft. the ground to be excavated was very porous, with open seams as wide as 8 in. It was feared that, when the next shot was made, there would be such a great inflow of water as to flood the shaft again. It was then decided to attempt to cut off the water by grouting the water-bearing seams.

For this purpose, twenty-seven vertical holes were drilled from 14 to 20 ft. deep, around the bottom of the shaft, each hole being fitted with a pipe and valve. A total of about 3 000 bags of cement was forced into these holes. At first, the grout leaked back into the shaft, but after some experimenting, the seams were finally clogged by mixing bran, oats, and ground horse manure with the cement. This grouting was so successful that it was decided to attempt to grout the remainder of the water-bearing strata in a single operation down to the top of the Shawangunk grit, a hard quartz conglomerate encountered in sinking the lower portion of the shaft. Six diamond drill holes, 1 in. and 2 in. in diameter, were drilled around the perimeter of the shaft for a depth of 100 ft. The holes were grouted under a pressure of 275 lb. per sq. in., but only 175 bags of cement could be forced in. After further delays, due to pump troubles, sinking was resumed. In the first 15 ft. exca-

vated, numerous seams well filled with grout were encountered; the maximum thickness of the grout was 8 in., in an irregular open bed of sandstone. The leakage into the shaft at this time was 225 gal. per min., which increased to 350 gal. per min. at a depth of 280 ft. The water continued to increase in quantity to 525 gal. per min. at a depth of 320 ft., and was strongly charged with H_2S gas, which attacked the men's eyes and caused abrasions to develop into sores.

In the meantime, the pumps continued to give trouble and with the shaft filled with no less than ten of them at one time, and with air and discharge lines, it was almost impossible to carry on the sinking operations. Due to the breaking down of one of the station pumps in the shaft, the latter was flooded for the sixth and last time. After it was again unwatered, a large pump chamber was excavated in the side at a depth of 310 ft., and three steam pumps having a combined capacity of 1 050 gal. per min. were installed therein.

Sinking was then resumed (a pilot drill hole being kept well below the bottom) and all seams were grouted, none of them taking more than 50 bags of cement, until the grit was reached. At the contact with the grit, an additional flow of 125 gal. per min. entered through an old drill hole, increasing the total inflow to 850 gal. per min. The flow was cut off by injecting 350 bags of cement under a pressure of 275 lb. per sq. in. All water-bearing seams in the grit were grouted, the maximum quantity of cement used at any point being 100 bags. When the bottom was reached, the total inflow into the shaft was 610 gal. per min.

The method of grouting used in this shaft was, in general, as follows: A 2-in. pipe provided with a long nipple and a gate-valve was driven into the drill hole as far as possible. To obtain a tight packing around the pipe, wooden wedges, oakum and cement were freely used, and horse manure mixed with the cement was also frequently used to clog the openings. A battery of four to six Canniff grout tanks was set up at the top of the shaft and connected with the hole by a 2½-in. pipe. The air pressure for grouting varied from 100 to 275 lb., the former being obtained from the main air line, and the latter from a small Westinghouse "booster." A thin mixture was used at first, and the quantity of cement was increased gradually; if this mix continued to flow freely, sand was added until the pipe began to clog.

The grouting in this shaft was very successful, at one time cutting off a leakage of more than 400 gal. per min. A total of 1 163 bbl. of cement was used in the grouting in the shaft. The holes drilled for grouting were generally 30 ft. deep, which depth was probably too great, as the grout would fill the wide horizontal seams, while the finer seams, cut nearer the bottom of the drill holes, would only be grouted for perhaps a few inches from the holes, due to the fact that in these seams the grout would set hard, while the wide seams were taking grout freely.

It is believed that the grouting would have been even more effective if shallower holes, about 12 ft. deep, had been drilled, as such holes would have cut a smaller number of seams, with the result that the rock would have been more thoroughly impregnated, and the grout would have traveled farther out from the shaft. On other work the best results have been obtained by alternately drilling and grouting, using shallow holes for the purpose.

City Tunnel Shafts.—All the shafts of the City Tunnel were lined with concrete. Although considerable leakage was encountered in several during the sinking, the inflow was either completely cut off or considerably reduced by grouting the water-bearing seams. If these wet shafts had been timbered instead of having been lined with concrete, the excavation would have been more difficult on account of the excessive quantity of water that would have had to be handled.

Shaft 4, City Tunnel.—This shaft, on the south side of Jerome Park Reservoir, was sunk to a depth of 242 ft. in Fordham gneiss. The rock was sound, and the shaft was dry until a depth of 150 ft. was reached, when a flow of 150 gal. per min. was encountered while drilling holes in the bottom. In a short time, the quantity diminished to a constant flow of about 50 gal. per min. After the shaft, which had been flooded, was pumped out, the drill holes were plugged and the concrete shaft lining was placed to within a few feet of the bottom.

The drill holes were then grouted under an air pressure of from 100 to 225 lb. per sq. in., using a mix of about 16 lb. of cement to 1 gal. of water. A total of 46 bags of cement was used in this grouting, and the leakage was entirely cut off. Water under a pressure of 70 lb. per sq. in. was also struck at a depth of 181 ft., and the flow at this level too was cut off by grouting.

Pilot holes, 14 ft. deep, were then drilled and all struck water, which in some cases washed 1-in. fragments of rock from the drill holes, indicating the presence of a disintegrated seam. These holes were grouted, but they took very little cement. The shaft was sunk another 5 ft. without increase of water. The bottom of the shaft was then in disintegrated rock well grouted.

The next step was to drill a large number of vertical holes, 18 in. apart and 16 ft. deep, around the periphery of the shaft. The holes were grouted, one at a time, each hole taking about two batches of grout, except some at one side of the shaft through which the leakage was about 100 gal. per min. The water from these holes could not be shut off, and the leakage was taken care of by pumping. As the shaft was deepened, no increase of flow was encountered, and sound rock was reached at a depth of 200 ft.

The water-bearing ground below the 181-ft. depth showed a crushed fault zone with a maximum thickness of 8 ft. on one side, below which the rock was disintegrated to a depth of 4 ft. A total of approximately 1 000 bags of cement was used in grouting this stretch, and although the disintegrated ground was found to be well impregnated with grout, the flow of water could not be entirely cut off. Thick grout was generally used, but it is believed better results might have been secured by the use of thin grout. After the shaft had been completely lined, the water-bearing seams were grouted through pipes set in the lining, and the leakage was reduced to 3 gal. per min.

Shafts 20 and 21, City Tunnel.—Shaft 20, 750 ft. deep, in the lower part of Manhattan Island, was excavated in Fordham gneiss which was generally dry. No trouble with water was experienced until a depth of 425 ft. was reached, when a flow of 30 gal. per min. was struck in the drill holes in the bottom of the shaft. Deep holes were drilled, pipes inserted, and a concrete blanket 2 ft. thick was placed over the bottom of the shaft. Grouting was started too soon, before the concrete had set hard, and it was necessary to add another 2-ft. layer of concrete. After a lapse of 48 hours, the holes were grouted under a pressure of 300 lb. per sq. in., and the water was cut off. No further trouble was had in excavating the remaining depth of the shaft.

Shaft 21 was sunk in granodiorite to a depth of 757 ft. at the East River, in the lower part of Manhattan Island. The rock was hard and

seamy, and wet zones were encountered about every 60 or 80 ft. The wet seams were grouted successfully in every case. A concrete blanket was placed over the seam to be grouted, as at Shaft 20, to retain the grouting pressures, and the results were satisfactory. The concrete lining in the shaft was placed in stretches of about 50 ft., as the sinking progressed, and any water entering through the grout pipes set in the lining was grouted off, in order to keep the bottom of the shaft as dry as possible.

Shafts 22 and 24, City Tunnel.—Shaft 22, in the Borough of Brooklyn, was sunk through gneiss and granodiorite. Only small quantities of water were handled, except at Elevation —430, where a flow estimated to have been 200 gal. per min., was encountered in a drill hole. The flow was controlled by inserting a pipe provided with a valve in the hole, after which other holes from 5 to 20 ft. deep were drilled to locate the extent of the water-bearing area, which was found to be on one side of the shaft.

The first attempt at grouting was unsuccessful, due to the large number of seams. A concrete blanket was then placed around two of the pipes, in the wet portion of the shaft, and the water was cut off by grouting under a pressure of 350 lb. per sq. in., only 6 days after it was first struck. Subsequent excavation showed that seams not more than $\frac{1}{16}$ in. wide were filled completely with cement. These seams were sharply defined cracks in the hard rock and were cut by the drill holes in such a manner as to provide good circulation of the grout, with the result that the grouting was successfully completed in a few shifts.

The granodiorite and gneiss through which Shaft 24 was sunk was blocky and more or less crushed. Little trouble was encountered in handling the water in the shaft, except in a stretch of 40 ft. at a depth of about 300 ft., where a flow of 240 gal. per min. was struck by one of the drill holes. The shaft was flooded, and it became necessary to install a large pumping plant to unwater it. After it was pumped out, the hole through which the water issued was plugged, and fourteen holes were drilled around the periphery of the shaft, varying in depth from $7\frac{1}{2}$ to $17\frac{1}{2}$ ft. Through pipes fitted into these holes, 55 cu. yd. of grout was forced into them under pressures as high as 325 lb. per sq. in.

The grouting of the wet seam caused the water to rise in the rock and flow from the smaller seams above. Holes were drilled into these seams, and grout under low pressure was forced into them, wedges of soft wood being driven into the seams where necessary to prevent the grout from escaping into the shaft. The leakage from these seams was reduced from 50 to 15 gal. per min.

On resuming excavation, it was found that the seam which yielded the large flow had been successfully grouted and gave no further trouble, but, after the smaller seams above had been closed, the rock in the shaft scaled so badly that it was necessary to suspend sinking and place the concrete lining. The leakage remaining was taken care of by pipes set in the concrete and subsequently grouted.

Grouting Behind Caissons, City Tunnel.—Before ledge rock was reached, the six southerly shafts of the City Tunnel had to penetrate through a deposit of water-bearing sand, varying in depth from 43 to 150 ft. The earth portions of these shafts were excavated by reinforced concrete caissons sunk by compressed air.

In order to effect a tight seal at the surface of the rock, the caissons were sunk from 2 to 5 ft. below the lowest point of sound rock around the cutting edge, and the space between the caisson and the rock was grouted through pipes set in a concrete bench on which the cutting edge of the caisson was sealed. Pipes were also placed through the concrete above the bottom of the caisson for the purpose of grouting the sand surrounding the caisson. The work was successful, as the leakage from the seal, after taking off the air, was only 7 gal. per min. at the deepest caisson, that at Shaft 23, where the hydrostatic head was more than 100 ft., and, subsequently, all this leakage was grouted off.

The experience in grouting the sand behind the caissons indicated, as found on other work, that little can be done to consolidate a mass of sand by attempting to fill the voids in it by grouting, but very good results can be obtained by grouting in filling voids due to loss of ground.

Grouting Closures of Construction Shafts.—The construction shafts which were sunk solely to expedite the excavation of the pressure tunnels, were closed by filling them, for a depth of about 50 ft. above the waterway of the tunnel, with concrete. These shafts were rectangular in shape, measuring about 10 by 22 ft., and were tim-

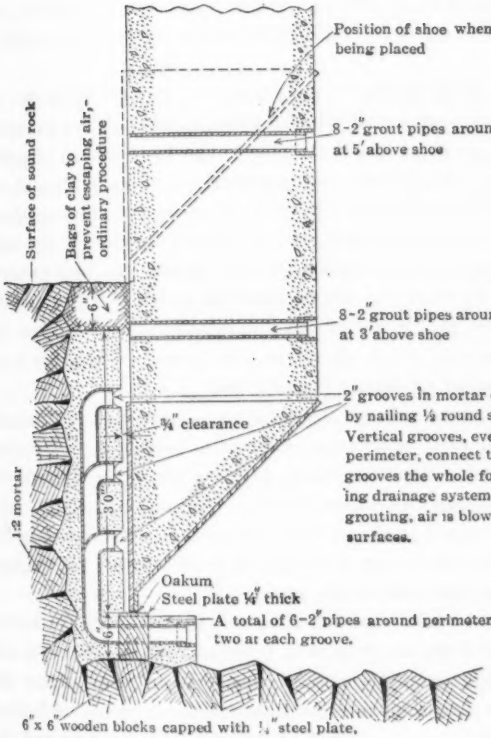
bered. Before the concrete plug was placed, the timbering in the bottom 50 ft. was removed, and the concrete was placed solidly against the rock.

It was realized that the concrete in the plug might shrink and leave a space between it and the rock through which the water from the tunnel would escape to the surface. In order to permit the filling of the shrinkage space, grouting channels were left entirely around the shaft at the top of each lift or at vertical intervals of about 10 to 15 ft. These channels were formed by placing sheets of tin or sheet iron around the shaft, the bottom edges of the tin being left in the fresh concrete, while the upper edges were wedged tightly against the rock.

Each grouting channel was provided usually with three 2-in. pipes set in the concrete; one, acting as a vent or drain pipe, extended down to the tunnel and two were carried up to the top of the plug. The channel was kept from clogging during the placing of the concrete by flushing it with water through the pipes leading to the top of the plug. After the concrete had set and shrinkage had taken place, the channels were grouted from the top of the plug, beginning with the lower one and working up.

The usual procedure before injecting the grout was to apply air pressure to each of the two pipes leading up from the grouting channel. While one pipe was being blown out, the other was kept closed, so as to wash any water or accumulation through the down drain pipe into the tunnel. Neat cement grout was then forced into one of the pipes until it showed at the vent pipe in the tunnel; the vent was then closed, and grouting was continued until the grout flowed from the top of the other up pipe. The latter was then closed and grouting continued, until no more grout could be forced in under a pressure of 300 lb. per sq. in. The high pressure was then applied to the other up pipe, and the process was continued until all the channels were grouted.

There is some question as to whether grout can be forced into the fine shrinkage space that may develop between the concrete plug and the rock. In Shaft 3, Rondout Pressure Tunnel, where it was necessary to excavate the plug in connection with the repair work in the tunnel, there were no indications of any layer of grout between the concrete and the rock. The concrete was found to adhere closely



6" x 6" wooden blocks capped with ¼" steel plate, placed at 4' intervals to receive shock of dropping caisson. Five inches of oakum placed under the entire perimeter prior to dropping, to insure water tightness. After caisson is dropped, grouting is immediately started.

3'0" collar may be reduced to 2'0" collar depending on rock conditions and ground water level.

to the rock surface. Grouting pans are of advantage, however, in protecting the concrete from water seeping into the shaft. If the water is not collected, it will find its way through the concrete, or between the concrete and the rock, resulting in injury to the concrete or to the bond.

In Shaft 6, Rondout Pressure Tunnel, 63, 45, and 53 batches of neat cement grout were forced into the lower, middle, and top grouting channels, respectively, of the shaft plug. The total volume of grout injected, namely, 161 batches, corresponding to about 200 cu. ft. of grout, exceeded the estimated volume of space in the grouting channels, so that it is believed that some of it penetrated into the rock seams. There was also indication of this during the high-pressure grouting of the top channel. Grout appeared in the rock seams above the plug and also at the top of the plug at the contact between the concrete and the rock, 19 ft. above the top channel. The grout leaks clogged up as the air pressure was continued.

In grouting many of the construction shaft plugs, no trouble was experienced, after connecting to a pipe leading to a grouting channel, and closing all other vents, to force air either through the rock itself or through the contact between the concrete and the rock. The fact that the air pressure could be kept at 100 lb. during the previously mentioned test, or raised to a higher pressure, showed that the seams and openings were very small.

It is important while removing the shaft timbering, in connection with the placing of the concrete plug, to take down all loose rock and place the concrete against the solid rock. It is possible that the passage of air occurring during the tests previously noted, took place through loose rock seams instead of between the concrete and the rock. Not only should loose rock be removed, but also all rock that sounds "drummy" when pounded.

The concrete plugs at the bottom of the construction shafts proved to be very tight against outward leakage.

Grouting Closures in Riser Valve Shafts.—The City Tunnel shafts through which water is supplied from the tunnel to the valve chambers at the top of the shafts, are provided with riser valves which are about 100 ft. below the top of sound rock. These valves are designed to close automatically if a break occurs in the valve chamber or in the street main. Below them, the waterway is a 14-ft., or larger,

concrete-lined shaft, and, above them, the 4 or 6-ft. riser is a mortar-lined steel pipe, embedded in a solid plug of concrete forming the shaft closure. The concrete plug was placed inside of an outer shaft lining of concrete, the latter having been placed during the sinking of the shaft.

Grouting rings or channels were formed at frequent intervals, when placing the plug concrete, to permit the grouting of the shrinkage space between the new and the old concrete. These channels were grouted after the concrete had been in place a sufficient length of time to insure complete shrinkage.

The procedure in Shafts 15 and 16 was typical of the practice in the City Tunnel shafts. In these two shafts, three grouting channels were formed between the concrete plug and the outer lining, the lowest one being about 5 ft. above the point where the plug started, and the others about 10 and 20 ft., respectively, above the bottom one. The channels were formed at the end of the day's work by placing segmental timbers of 4 by 4-in. cross-section in the top of the green concrete, around the perimeter of the plug.

Two 2-in. pipes, placed diametrically opposite, were carried from the bottom of the plug to the bottom of each grouting channel. Before starting to place the next lift of concrete, the channel was covered with sheet iron bent against the outer lining and covered with a sloping layer of stiff concrete about 1 ft. thick. The latter protected the sheet iron and kept it from being displaced.

After the concrete plug had set six weeks, the channels were grouted. The general procedure in each case was to blow out the pipes and channels with compressed air at pressures of 50 to 60 lb., after which water was forced through, and, finally, grout was injected under pressures up to a maximum of 150 lb. per sq. in. The grout used varied from a mix of 1 volume of cement to 8 volumes of water to one of equal volumes of cement and water. The experience at these shafts showed a slight passage of water and grout from channel to channel, but no evidence of leakage showed around the plug at the top of the shaft.

In Shaft 24 of the City Tunnel, four grouting channels were provided in connection with the placing of the concrete plug which is 197 ft. deep and 24 ft. in diameter. To each of the two lower channels, three 2-in. pipes were carried from the shaft below the plug,

and from the two upper channels, three pipes were carried to the top of the plug. Compressed air was forced into the pipes of the lower channels before any grouting was begun. The air circulated freely between the plug and outer lining, appearing at the surface.

The bottom channel was grouted first, the grout being forced into the pipes until they refused it under 300 lb. pressure. The grout from the lower channel flowed upward into the next channel and its pipes, but reached the top of the plug through the pipes of the upper channels. Connection was made to each pipe, the lower channels being completely grouted before the upper ones were begun.

The results obtained at all the City Tunnel shafts have been very satisfactory, as there has been no leakage into any of the chambers at the top of the shafts. At some of the shafts, the pressure of the water at the level of the chamber floor is about 110 lb. per sq. in.

Grouting Under the Foundations of Dams and Dikes.

Grouting Seams in Rock Under Olive Bridge Dam.—The masonry portion of this dam is about 1 600 ft. long, and rises to a maximum height of 210 ft. above the bed of Esopus Creek. The bluestone layers underneath the creek were excavated to sound rock at a maximum depth of about 25 ft., and, in addition, a cut-off trench about 20 ft. wide was excavated, to a maximum depth of 40 ft., across the creek channel just below the up-stream edge of the dam. Below the top layer of bluestone, alternating layers of slate, shale, and bluestone were found, the beds varying in thickness from 1 to 15 ft.

Before excavation for the dam was started, the rock underlying the foundations was explored by means of fifteen diamond drill borings from 40 to 100 ft. deep, put down in the bed of the creek and the adjacent rock sides. The holes were tested by hydrostatic pressure tests for the purpose of locating the position and permeability of the seams in the rock. These investigations showed two definite planes of leakage at depths of 40 and 60 ft. below the bed of the creek.

To prevent the flow of water through the open seams, a total of 217 holes, 2½ in. in diameter, were drilled to about 1 ft. below the seams for the purpose of grouting them. The lower seam was reached by a row of 45 holes, spaced about 5 ft. apart, drilled from the bottom of the cut-off trench. For grouting the upper seam, seven rows containing 172 holes, also spaced 5 ft. apart, were drilled from the bottom

FIG. 10.

of the excavation down stream from the cut-off trench. A model was made, showing the position of the grout holes and the water-bearing seams, and was found to be useful in connection with the subsequent grouting.

A 3-ft. length of 2-in., wrought-iron pipe, the lower end of which was chipped with a chisel and wrapped with jute, was driven into the tops of the holes until the jute became firmly wedged and made a tight joint. The pipe was then wedged fast at the top with two small iron wedges, and the annular space between it and the sides of the drill hole was filled with grout, thus sealing the pipe in the hole. If water was flowing from the drill hole, the iron wedges and the grout were omitted, and dry cement was rammed into the top of the hole outside the pipe.

Sections of pipe of convenient length were successively screwed to the tops of the grout pipes so as to keep them always above the top of the cyclopean masonry as the latter progressed, until the holes were grouted. After the surface of the rock was covered by a sufficient weight of concrete masonry to overcome the possibility of lifting or blowing out by hydrostatic pressure, the tops of the grout pipes were connected to a Cockburn grouting machine of about 4 cu. ft. capacity, and grout was forced into the hole by an air pressure of from 25 to 90 lb. per sq. in. The grout generally used was mixed in equal volumes of neat cement and water.

The grouting extended over a period of about one year and was done at any convenient time after the concrete had attained a height of 10 ft. or more. The 45 holes extending to the lower seam took a total of 251 cu. ft. of grout, of which it was estimated that 175 cu. ft. entered the seam. The 172 holes drilled to the upper seam received a total of 1 118 cu. ft. of grout, of which it was estimated that 925 cu. ft. entered the seam.

The quantity of grout forced into any hole varied from 0 to 198 cu. ft., and only about 10% of the total number of holes took an appreciable quantity. The maximum distance through which grout was forced, making its appearance in other pipes, was 70 ft.

A number of experiments were made in connection with the grouting, which are of interest. Grout was forced under a pressure of 25 lb. per sq. in. into a hole drilled about 15 ft. back from the edge of the cut-off trench, and appeared on the face of the trench from a

horizontal seam about 6 in. below the top. Several months later, the rock covering this seam was barred and wedged off, and the seam appeared to be well filled with cement which was set hard.

Grout was also forced into a drill hole about 6 ft. back from the face of the cut-off trench, through two seams to the face of the trench. Two days later the rock was barred off, exposing the seams which were found to be well filled for a distance of 4 ft. in every direction from the hole, and partly filled 2 ft. farther out.

Grouting at Woodstock and Glenford Dikes.—These two structures close the gaps between the hills forming the Ashokan Reservoir. The dikes consist of rolled embankments with center concrete core-walls which, with the exception of short portions, were carried down to ledge rock. In the vicinity of the dikes, the rock is overlaid with a cover of clay and gravel, varying from 1 to 30 ft. in depth.

As the East Basin of the reservoir filled, it was observed that some seepage was taking place underneath the dikes, which increased as the water level in the reservoir rose. Although the loss of water was not serious, it was considered advisable to take measures to stop the seepage and to improve the character of the foundations. To determine to what extent this might be accomplished, it was decided to grout a portion of the foundation of the Woodstock Dike.

Operations were limited to a length of 379 ft., the total length of the dike being approximately 2 500 ft. Holes were drilled, spaced about 12½ ft. apart, on the center line of the dike where the core-wall extended to rock, and on a 5 or 6-ft. off-set line up stream from the center line, where the core-wall was not carried down to rock. Thirty-five holes were drilled, their total depth through the embankment and earth cover aggregating 426 lin. ft., while the depth of the core-borings totaled 717 lin. ft.

Where the holes were on the center line of the dike, a 4-in. casing was driven to the core-wall, a distance of approximately 9 ft. A 3-in. hole was then drilled into the core-wall to a depth of 2 ft., into which a 2½-in. casing was driven and grouted, giving a tight seal. The 4-in. casing was then withdrawn. For the holes up stream from the core-wall, a 2½-in. casing was driven to rock. The rock was chopped out to a depth of from 4 to 24 in. and the casing was driven tightly into it.

The core-borings were made with an **A** bit, which cut a hole of approximately 1⅞-in. diameter. The rock encountered was bluestone,

varying from a coarse stone of good quality to a very fine grained stone. In general, the holes averaged 40 ft. in depth, 20 ft. of this being in rock. Tests made by pumping water into the holes showed loss of water at practically all those drilled in rock, the maximum quantity that could be pumped into a hole without accumulating pressure, having been 66 gal. per min.

On the completion of the drilling, the holes were grouted. Two Cockburn-Barrow grout machines were used to mix the grout, discharging into a wooden box, from which it was pumped by a Douglas hand grout pump into the hole to be grouted. The mix varied in consistency from ½ bag of cement and 40 gal. of water to 5 bags of cement and 40 gal. of water. The general method of procedure was to attach the grout pump to a hole and continue pumping in grout as long as the hole would take it. In the majority of cases, the grout did not show in adjacent holes. In one instance, however, it appeared in a hole 37 ft. distant from the one grouted.

On the completion of the grouting of the rock, the casing was first pulled about 12 to 18 in. and grout was then pumped in, keeping the pressure at a maximum of 7 lb., except that after work had been done on a hole and then resumed after an interval, a slightly higher pressure was used for a short time. When the hole would take no more grout, the casing was pulled another 18 in., and the grout applied once more to refusal. This procedure was continued, alternately pulling casing and grouting, until the casing had been raised so that the bottom was at the elevation of the flow line.

The maximum quantity of grout forced into a hole in the rock was 1 078 bags of cement and the minimum 13 bags. The maximum quantity forced into a hole in the earth cover above the rock was 496 bags and the minimum 20 bags. A total of 1 881 bbl. of cement was used in this experimental grouting. It resulted in an appreciable reduction in the amount of seepage for the portion of the dike treated. Measurements made soon after the completion of the grouting, indicated a reduction of approximately 50% in the amount of seepage.

In view of the satisfactory results obtained in grouting the experimental section, it was decided to grout the foundations of the Woodstock and Glenford Dikes for their entire lengths, except a few sections which it was thought unnecessary to treat.

FIG. 11.—GROUTING SEAM IN ROCK, 60 FT. BELOW THE CREEK BED, UNDER OLIVE BRIDGE DAM.

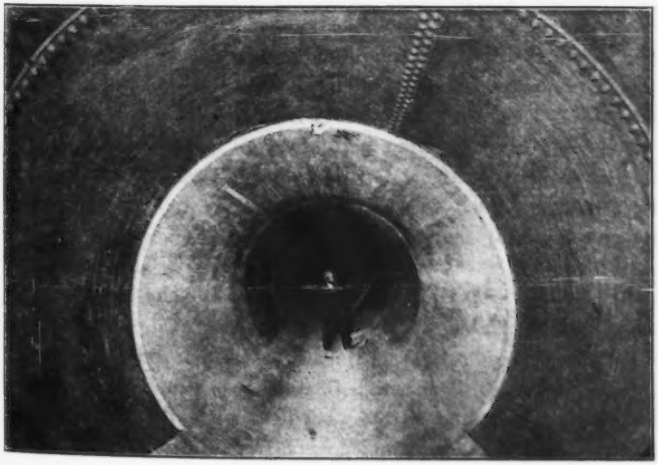

FIG. 12.—MORTAR LINING IN STEEL PIPE SIPHON, 2 IN. THICK, PLACED BY POURING GROUT FROM SURFACE.

A modification was made in the procedure originally followed. Where the core-wall was founded on rock, the holes were drilled in two rows, 2 ft. apart, spaced about 20 ft., center to center, in each row, the holes being staggered. In the Woodstock Dike, the holes were drilled through the core-wall and into the rock, the method of sinking and sealing the casing being the same as that described in the experimental work. At the Glenford Dike, it was impossible to drill holes through the core-wall because of the location of the Ulster and Delaware Railroad on that dike; the casings, therefore, were sunk up stream from the core-wall, with the same spacing as described previously.

For the portions of the Woodstock Dike where the core-wall was not carried to rock, holes were placed on offsets and spaced 5 ft. apart; 4-in. casing was sunk to rock, and, at alternate holes, 2½-in. casing was placed inside the 4-in. casing and securely sealed into the rock. The holes through the core-wall and into the rock were $2\frac{1}{16}$ in. in diameter instead of 1¾ in., as in the experimental work, and were drilled to a minimum depth of 20 ft. into the rock. The total linear feet of holes drilled at Woodstock Dike, including the experimental section, was 11 182, and at Glenford Dike, 9 190.

The same general procedure was followed in grouting the holes as in the experimental grouting, but some changes were made. In order to economize in the labor incidental to the use of hand-pumping of grout, water pressure supplied by steam pumps was substituted for the Douglas hand pump, four grouting units being in operation at all times, with piping extending the full length of both dikes. As before, Cockburn-Barrow grout machines were used for mixing the grout, wooden troughs conveying it to hollow iron cylindrical pressure tanks.

These grout tanks consisted of 12-in. iron pipes, 4 ft. long, laid horizontally, two of which were mounted on a portable wooden truck. Suitable 2-in. pipes and fittings made it possible to use each tank alone or in sequence. Pressure, when required, was applied at one end by connection with the water line, and the grout in the tank was discharged by displacing it with water. This method was found to work very smoothly, resulting in a saving of time and more effective grouting on account of the continuous operation.

The grouting of the earth cover and embankment above the rock, at the Woodstock Dike, was completed before the rock was grouted. The row of 4-in. casing without the inner 2½-in. pipe, was grouted first, and then the other row, the grouting of cover to flow-line elevation being accomplished by raising the 4-in. casing as desired. After this cover grouting was accomplished, the 2½-in. casing was used to grout the rock. A total of 7 564 bbl. of cement was used for grouting at Woodstock Dike, including the experimental section, and 5 613 bbl. at Glenford Dike.

The results of the grouting at both dikes have been very satisfactory, the estimated reduction in seepage, with a full reservoir, being 75% at Woodstock Dike and 90% at Glenford Dike. In addition, the foundations under the dikes have been improved materially, due to the consolidation of the disintegrated rock and the filling up of the seams and cavities.

Grouting the Foundation Under Kensico Dam.—Kensico Dam is a gravity structure of cyclopean concrete masonry, with a maximum height of 310 ft. above the bottom of the excavation. The dam is across the Bronx River, between parallel ridges which rise to a height of about 180 ft. above the bed of the river. At the site of the dam, the quality and attitude of the rock was developed by core-borings which clearly revealed the geologic structure of the valley floor.

The east ridge is composed of gneiss, the west ridge of schist, and between the two hills lies a bed of crystalline limestone about 400 ft. thick. The excavation for the dam was carried down to generally sound rock. The limestone was found to be deeply decayed in places, especially along the contact with the gneiss, where the decay follows the contact for a depth of more than 100 ft. below the general level of the rock floor and affects the adjacent gneiss. No decay was found at the contact between the limestone and the schist. Both the gneiss and the schist showed less depth of decay than the limestone but, in places, these rocks were shattered and showed the effect of crush zones by lines of weakness along the bedding planes.

The foundation of the dam required more or less extensive grouting at three points, one in the schist near the west end of the dam, one at a soft seam in the limestone, and the third covering the entire east side of the gorge.

At the west end of the dam beyond the cut-off trench, the mica schist was found to contain occasional cross-bedding seams, and the area was explored by a few drill holes, 25 ft. deep, which were tested with water under pressure. Some intercommunication was found in these holes, although holes drilled in the bottom of the cut-off trench just east of this area were tight. The area was treated by drilling two lines of holes 11 ft. apart, with a 3-ft. spacing in each line, and 25 ft. deep, for a length of 40 ft. along the dam. After the masonry had been placed to a sufficient height, the holes were filled with grout under pressure.

At one place a crush zone in the limestone crossed the foundation. At the surface of the rock it was about 15 ft. wide, but it narrowed with depth. It was followed down by the cut-off excavation until it was less than 3 ft. wide, and as it was entirely filled with compact material, further excavation was deemed to be unnecessary. Holes 25 ft. deep were drilled over the area, and on testing with water and uranium, those to the west of the seam were observed to be more or less in communication with each other. When the masonry in the dam had been placed, providing a cover of 35 ft. or more in thickness, the holes were grouted.

On the east side of the gorge, where a disintegrated zone was found at the contact between the gneiss and the limestone, more extensive grouting was necessary than elsewhere. The rock lay in beds about 2 ft. thick, and when exposed the bedding planes opened up. Several layers were excavated until fairly sound rock was reached but, under exposure to the air and summer heat, a further opening of the bedding planes took place. The excavation of the cut-off trench, which was carried down to a depth of 40 ft. below the general level of the excavation, had shown that several seams in the rock were open and water-bearing.

Holes, 25 ft. deep and about 25 ft. apart, were drilled normal to the inclination of the strata, and 2-in. pipes were fitted into them and extended up through the masonry. Two rows of holes were also drilled in the bottom of the cut-off trench near the sides, about 15 ft. apart, longitudinally. The tops of the lower holes in the gorge were at about Elevation 65, and as they were not grouted until the concrete had reached Elevation 192, the grout pipes were in some cases 125 ft. in length.

Pressure tests, using water colored with uranium, were made on each hole to determine the influence on the other holes. As a result of the tests, it was concluded that the cut-off trench effectively intercepted the more open seams, and that the grout pipes could be divided into three groups: First, the holes up stream from the cut-off trench, where they all appeared to connect freely with each other; second, the holes in the cut-off trench which evidently penetrated a region not reached by the others; and, third, all the holes down stream from the cut-off trench, which were evidently quite freely intercommunicative.

In grouting, each of the three groups was treated separately. Usually, the pipe which took water most freely was the first to be grouted. As the grout appeared in other pipes, they were capped, and the pressure continued until the hole refused to take more grout. Then the pipe was capped, and connection was made to another pipe, the uppermost pipe being left open for a vent. Eventually, all the pipes were filled with grout, capped, and left embedded in the dam masonry. With the reservoir full for two years, there has been no indication of any leakage on the down-stream side of the dam.

Miscellaneous Grouting.

Mortar Lining Inside of Large Steel Pipes.—Steel pipe siphons were used for crossing valleys along the line of the aqueduct where the rock was not sound or where, for other reasons, pressure tunnels would be impracticable. The steel pipes vary from 9 ft. 6 in. to 11 ft. 2 in. in diameter, and are lined with 2 in. of cement mortar, enveloped with concrete, and covered with an earth embankment.

The mortar lining was placed in two operations (see Fig. 12): First, an invert about 8 ft. wide was placed in the bottom of the pipe, using a 1:2 mortar and finishing with a screed board and trowel; and, second, the portion above the invert was lined by using a wooden form built up of curved panels inside the pipe, and pouring grout from the surface of the ground through vertical 2-in. pipes screwed to the top of the pipe at 15-ft. intervals, one pipe being used to grout a 15-ft. section and the next for a vent.

The grout was mixed by hand on the surface in boxes arranged so that one batch would be mixed while the other was discharged. The grout was poured through the pipe screwed into the lower hole, until it ran out of the 4-ft. riser inserted in the upper hole. The pouring

was continued for some time to allow the air to escape. This method permitted the discharge of the surplus water and laitance, and effectively took care of any shrinkage. The grout for the portion between the invert and the springing line was mixed 1 : 1, while, for the portion above the springing line, a 1:2 mixture was used.

In one of the siphons, the mortar lining was placed by the cement gun, without the use of forms. The apparatus consisted of a double tank with air-tight bulkheads and a revolving feed for sand and cement. The mixture was discharged by air under 40 lb. pressure through a rubber hose. As the mixture reached the nozzle, it came in contact with water discharged through another hose, and the combined spray was discharged with great force against the inside surface of the steel pipe. Although the results obtained with the cement gun were satisfactory, it was not well adapted for the work and was not used subsequently in the other siphons.

Grouting Expansion Joints in Cut-and-Cover Aqueduct.—The concrete in the arch of the cut-and-cover aqueduct was placed in lengths of 30, 45, 60, and 75 ft. The vertical expansion joints at the ends of the arch sections were formed either by tongue-and-groove joints cast in the concrete, or by steel plates. Owing to temperature changes, these joints opened up in cold weather, the width of the openings varying from about $\frac{1}{32}$ to $\frac{1}{4}$ in., depending on the temperature of the air and on the length of the arch sections. Hydrostatic tests, made by filling portions of the aqueduct, showed that neither the tongue-and-groove nor the steel-plate expansion joints were tight against outward leakage in all cases. After some experiments and tests, it was decided that the most effective method of making the joints tight was to grout them with cement. Accordingly, the joints in several miles of aqueduct were treated by grouting them in the winter months when they are open the widest. Only the joints that were appreciably open were grouted.

The following method of grouting was found to be successful on one section of the work. The grout from a 2-qt. tin coffee-pot was poured into a small tin funnel and through a $\frac{1}{2}$-in. rubber tubing, about 12 in. long, into the joint. The joints were usually raked out in advance of the grouting, using a 12-in. pruning saw having very coarse teeth on one edge. The grout was poured near the top of the

joint, from the inside of the aqueduct, the leakage of grout into the aqueduct being stopped by caulking the joint, usually with oakum.

Where the joints were wet, on account of inward leakage due to ground-water, it was necessary to grout them by pressure, using a Douglas hand pump for this purpose. They were first drilled by hand at convenient points, and into the holes were inserted ¾-in. pipe nipples, 6 in. long, threaded at one end. The nipples were caulked into the joints with lead wool, and the inside edges of the joints were also caulked with the same material.

The mix generally used for grout poured into place was 5 parts of cement to 8 parts of water by volume. This consistency was found to be a little too thick for the hand pump and, for the wet joints, a mix consisting of 3 parts of cement to 8 parts of water was used. The grouting was very effective in making the joints tight against leakage.

Grouting Caving Ground in the Grade Tunnel.—In driving one of the headings of the Reynolds Hill Tunnel, several slips occurred, and, in a 15-ft. stretch, the timbering was badly distorted by the slide. In order to excavate safely the bench through this section, the space outside the timbering which had previously been dry packed, was grouted. Concrete was first placed back of the timbering for a height of about 4 ft. above the wall-plates and, at each end of the section, concrete cut-off walls were built as high as possible between the lagging and the rock, the closures being made with brick masonry. The dry-packed space over the arch between the cut-off walls was then grouted by a tank grouting machine. More than 30 cu. yd. of 1:1 grout were placed. No trouble was experienced subsequently in excavating the bench through this section.

Grouting in Tunnel Where Concrete Lining Had Disintegrated.—Some time after it was placed, the concrete lining in a portion of the Eastview Grade Tunnel was found to be undergoing a progressive slow disintegration, caused by the infiltration of the surrounding ground-water which contained certain chemical elements injurious to concrete. The portion of the tunnel affected, a stretch of about 1 700 ft., was relined with brick 12 in. thick.

To take care of the water seeping through the concrete lining, sheets of steel were used throughout the side-walls and arch of the lined section, and kept uniformly away from the concrete face by

ordinary spruce plaster lathe, to provide drainage and grouting space. Before the brick lining was placed, a bituminous water-proofing fabric was deposited on the sheet metal water-stop and on the invert concrete.

Along the center line of the invert, in the lined section, a 4-in. tile pipe was laid with open joints to receive the drainage water. Transverse drainage grooves cut in the invert conveyed the water from behind the metal stop to the center line drain. This drain was provided with 2-in. pipes, 12 in. long, extending up through the brick lining on the invert. Before grouting the space behind the water-stop, this drain and the connecting grooves were pumped full of grout, connections being made to the 2-in. pipes in the invert.

For grouting between the metal stop and the original concrete lining, 2-in. pipes were set, extending through the brick work at three levels on both sides of the tunnel. The grouting was done in successive upward stages, grout being supplied to the lower middle and upper level of pipes until it appeared at the next higher level, each stage covering the entire length of lined section before the next stage was begun. A Douglas hand pump was used to place the 1 : 1 grout which was mixed in boxes carried on flat cars and stirred continually while being used. On account of the hydrostatic pressure behind the brick lining, the side-walls were braced throughout the length of the lining during grouting, with 4 by 6-in. struts, spaced 5 ft. on centers, and wedged in place.

In addition to relining a portion of the tunnel with brick, additional precautions against the disintegrating effect of the ground-water were taken by grouting the space above the arch for the entire length of the tunnel, about 1 mile. This space in the roof between the concrete and the rock had been partly dry packed at the time the concrete lining was originally placed.

The grout pipes were 1½ in. in diameter, provided with couplings at their ends, and placed in holes drilled through the concrete. A pair of pipes, one a grout and the other a vent pipe, was placed through the arch concrete at intervals of about 50 ft. The inner ends of all pipes were wrapped smoothly with cotton cloth in order to make them fit tightly in the holes, and were driven in place by a sledge-hammer.

The grout, consisting of 1 bag of cement, 1 bag of sand, and usually 12 gal. of water, was placed by means of a Canniff tank, the

grout being forced in to refusal under about 90 lb. pressure. The quantity of grout placed averaged ½ cu. yd. per lin. ft. of tunnel.

General Conclusions in Regard to Grouting.

The experience in the grouting operations in connection with the Catskill Water-Works, showed that grouting is very effective for backing up, and filling the spaces behind, tunnel linings. A mixture consisting of 1 bag of cement, 1 bag of sand, and from 6 to 8 gal. of water, was found to be well adapted for this purpose. The air pressure should not be greater than is necessary to force the grout into place. The pressures actually used varied from 30 to 90 lb. per sq. in. To complete the filling of the voids between the tunnel lining and the rock, particularly in the high places in the roof adjacent to the "vent" pipes, air pressures up to 300 lb. per sq. in. and neat cement grout were used.

Good results were obtained in cutting off the leakage of water into the tunnels by grouting the water-bearing seams. For this purpose, it is essential to control the inflowing water by collecting it behind drip-pans or a steel shell, and draining it by pipes through which the grout is subsequently forced into the seams. Neat cement grout, about 6 gal. of water to 1 bag of cement, was found to be effective for this purpose. For fine openings a very thin mix must be used in order to obtain good results. The pressures should be sufficient to overcome the ground-water head and force the grout into the rock.

In sinking wet shafts, grouting was successful in cutting off leakage. The best results were obtained by alternately drilling and grouting, using holes about 10 to 15 ft. deep in the bottom of the shaft. The consistency of the grout should be adjusted to the size of the seams. In some cases, a little addition of bran, oats, etc., to the neat cement grout will aid in plugging the crevices in the rock.

The results obtained in treating the foundations of dams and in cutting off leakage underneath the dikes by drilling holes and grouting the rock seams under the dam structures were satisfactory. It is desirable in such cases to explore the rock under the dams thoroughly by diamond drill borings for the purpose of locating weak zones and open seams. The location of the holes and method of grouting will depend on the natural conditions encountered.

In conclusion, it should be stated that the procedure to be adopted in any grouting operation must take into account all the factors that enter into the problem. No one method is applicable to all cases. The conditions encountered during the grouting may make it advisable to modify the procedure materially. Good judgment and skillful adaptation to meet varying conditions are essential to a successful conclusion.

This paper was prepared at the suggestion of the Chief Engineer, J. Waldo Smith, M. Am. Soc. C. E., to whom the writers are indebted for advice and many valuable suggestions. Many of the data were obtained from reports and contributions by members of the staff of the Board of Water Supply of New York City, and the writers wish to express their appreciation of the assistance given them, particularly by A. D. Flinn, Robert Ridgway, G. G. Honness and M. H. Freeman, Members, Am. Soc. C. E., L. White, Assoc. M. Am. Soc. C. E., and Mr. L. B. Stebbins.

DISCUSSION

Mr. Ridgway.

ROBERT RIDGWAY,* M. AM. SOC. C. E.—The speaker wishes to express his appreciation of the great value of this paper to constructing engineers. Not only is the subject one of much importance, but the authors are especially qualified to present the paper because of their first-hand knowledge of the operations which they describe. Its value is enhanced by the fact that it was prepared while the work was still fresh in mind, in consultation with those familiar with all the details of the operations and with all the records available. Many lessons learned at great cost on works of construction are lost to those who take up similar work at a later period because the organization that learned and applied them is broken up on completion of the work, leaving behind only what a recent writer has described as "dead and fragmentary records" which are practically lost when they are filed away in some vault for safe keeping. The construction of large water supply systems like those of the Catskill project is not a continuous performance. Sometimes there are intervals of many years between the completion of one project and the beginning of another, and the earlier work is largely forgotten when the later one is undertaken. If a record of the unusual features of design and construction is not left behind in some such form as the paper under discussion, those who take up similar studies at some future time must go over the same ground and inevitably make some of the same mistakes as their predecessors.

The grouting methods of the Catskill work were highly developed, and were successful as a result of a willingness to experiment in practical ways and of the large experience gained on a work of such magnitude and varying conditions. It is extremely fortunate, therefore, that this interesting paper has been prepared describing the methods adopted, and it is hoped that the Chief Engineer will suggest to his staff the preparation of other equally valuable papers descriptive of such features of the work, for example as the deep pressure tunnels for which there was little precedent in earlier projects.

The speaker's first experience with grouting was in the grade tunnels of the so-called New Croton Aqueduct during the years 1888 to 1890. This tunnel was lined with brick backed with rubble masonry. The brickwork and rubble were laid at first in natural cement mortar, but in the later stages of the work Portland cement mortar was used. On account of the unfortunate conditions then prevailing, for which the engineers were in no way responsible, it became necessary to repair long stretches of defective masonry lining. It was the practice of some of the contractors to omit most of the mortar in the rubble masonry and in some cases to omit the rubble masonry altogether. The scamp work

* New York City.

Mr. Ridgway.

was done in such a wholesale manner that it was necessary to organize for the repairs in a comprehensive way. Where the brickwork was defective and where large voids existed in the backing, it was of course necessary to tear out and rebuild. Where it was a case of supplying the mortar in the rubble backing it was decided, after considerable discussion and experimenting, to resort to grouting methods.

An experimental period had to be passed through at first. Holes were drilled through the brick side-walls and a thick mixture of grout was poured into them by means of funnels. This method, of course, could not be adopted in the upper portions of the arch, nor could any pressure be applied to the grouting. Besides, it was a retail way of doing a wholesale job and was soon discarded.

The method later adopted, and which proved to be successful for the work in hand, required the use of hand-operated Douglas pumps. A 1 : 1 mixture of natural cement and sand was mixed by hand in open boxes and pumped through holes drilled in the brickwork. Natural cement, or as it was then called, "American" cement, was used because much of the masonry was specified to be laid with that cement. In order to insure practically continuous pumping two boxes were used, the mixing going on in one while the charge was being pumped from the other. A set of nine holes was drilled every 10 ft. in the side-walls and the arch. The metal nozzle of the discharge hose, wrapped with cloth or burlap, was driven into these holes and the grout was pumped in to refusal. Generally, four men were used at the handles of the pumps, the number being increased to six when the pumping was hard. The lower holes on each side were grouted first and the key holes last. The grout was driven long distances, sometimes several hundred feet, and frequently was lifted over the arch from the lower holes in the side-walls. Grouting in one hole frequently blocked many others, but the latter were subsequently tried and sometimes took an appreciable amount of grout.

Prior and subsequent to the first grouting the masonry was carefully sounded with steel rods for indications of cavities or other defects. Those engaged on such work soon became very expert and could tell in a general way from the tone given out by the rod whether or not the brickwork and its backing were defective. Where the soundings or the drill holes, together with the cross-sections, indicated the existence of large cavities, or where the brickwork was defective, test holes were cut and the defective work removed and rebuilt as far as necessary before any grouting was done in the vicinity. After the first grouting, another set of holes was drilled and grouted where soundings indicated that further work was necessary. Again the work was sounded, and a third grouting was done in the limited number of places requiring it.

In the report of the Aqueduct Commissioners for 1887 to 1895 is a general description of this grouting by the Chief Engineer, and a state-

Mr. Ridgway.

ment is made by him that 384 700 bbl. of cement in all were used for grouting, exclusive of the cement used for the reconstruction of defective or missing masonry by hand. Of this amount probably 15% was wasted through leakage and other causes. As the purpose of the work was to fill voids in the masonry backing, no attempt was made to grout seams in the rock. The methods were crude as compared with those used on the Catskill work, but accomplished the results desired. Although the voids were almost completely filled with grout it appeared from the speaker's observations that the latter did not set up well. Samples taken out by him a year or so afterward showed the natural cement to be of chalky consistency, with little strength. Apparently, natural cement is not suitable for grouting work except in cases where its function is merely to fill voids. Where strength and density are essential requirements only Portland cement should be used.

Grout was used extensively and successfully in the construction of the tunnels of the subway system of New York City. This grouting was important, but generally speaking it was not of such difficult character as that of the Catskill work. In earth and rock tunnels, grouting was done to fill the voids which always exist over the concrete arch and to reduce leakage. It was done in the soft ground shield-driven tunnels adjacent to the East River to prevent settlement of ground overhead, and where the work was done in compressed air under and in the vicinity of the East River to reduce the loss of air from the tunnels. The methods have been quite successful in accomplishing these objects. The pressures used have not been high, corresponding to those used in the "low-pressure" grouting described by the authors.

Within the past year, grouting was successfully used to reduce the leakage in the Canal Street Station of the New York Municipal Railway subway from considerably more than 100 gal. per min. to less than 2 gal. per min. The work was of a most difficult nature and the excellent results were accomplished only because the engineers in direct charge were possessed of an intimate knowledge of modern grouting methods and their limitations. The speaker will not go into the details, as he understands that they have been covered in the written discussion by A. J. Mayell, Assoc. M. Am. Soc. C. E., who was the Assistant Division Engineer on the work. The guidance of M. H. Freeman, M. Am. Soc. C. E., formerly of the Engineering Staff of the Board of Water Supply, was invaluable on this work.

It is apparent from the authors' description that the concrete of the tunnel and shaft lining is of excellent quality, due to the great care taken in placing it. Otherwise, the speaker is convinced that the grouting would not have been a success. To accomplish the results described it was essential that the concrete be strong and dense. Grouting will not change poor concrete into good concrete and it adds little or nothing

Mr. Ridgway.

to the strength of poor concrete. To obtain good concrete it is necessary not only to mix it properly, but to keep all water pressure away from it while setting. It will be porous unless this is done, as many engineers have found when they have not taken proper precautions.

Grouting is expensive, and to secure the best results at the least cost and in the quickest time it is wise to employ only those experienced in such work. To start with an untrained force usually results in discouragement and sometimes the abandonment of the work. After the men are well broken in they seem to develop an instinct for doing the work in the right way in the shortest time and accomplish what before seemed to be impossible.

If the grouting work under a contract is to be done as carefully and as thoroughly as it was on the Catskill work it is necessary to draw the specifications with care and to make provision, as was done on that work, to pay the contractor for each step in the operations. For example, the cost to the contractor of moving the apparatus and of making connections to the grout pipes is considerable and sometimes many connections are made to pipes which take no grout. If payment is made merely on the basis of grout pumped in, this would work a hardship on the contractor who would receive no payment for the work done on those holes into which no grout was forced. In the case of the Catskill work payment was made under unit prices for each connection effected.

The authors state, referring to the cement, "experiments show that the finer the grinding, the greater the loss in the strength of the grout on account of the more thorough hydration of the cement. The coarse particles impart strength to the cement, and, for that reason, very fine grinding may not be desirable." This is interesting, and contrary to the idea of the speaker, who had been of the opinion that finely ground cement would be better for this and for all other purposes. Where sand is used it must be very fine, as the authors point out, to prevent segregation as well as clogging of the holes.

In the discussion preceding the preparation of the Catskill tunnel contracts the speaker favored the cut-off walls mentioned by the authors. It was believed that by confining the grouting to relatively short stretches of tunnel and completing each stretch before passing to another the cement and sand would not segregate and that better results would be obtained. Experience, however, showed that they did not work out well in practice and hence their use was discontinued.

The authors point out the care necessary to prevent a blast of air following the charge of grout where the tank machines are used. Where small spaces are to be filled completely and the amount of grout, consequently, is small, it has been found advisable in many cases to use a hand pump, thus avoiding the objection of trapping in the cavity air which prevents complete filling of the hole.

Mr. Ridgway. It has been assumed by many that grouting could be used to solidify unstable sand foundations, particularly where the sand is fine and saturated. The speaker has seen a number of unsuccessful attempts made to do this. Perhaps with infinite pains and at great expense something could be accomplished in this direction, but he does not believe it to be a practical proposition.

As of interest in connection with the treatment of dam foundations, attention is called to the paper by the late Charles S. Gowen, M. Am. Soc. C. E., entitled "The Foundations of the New Croton Dam",* wherein is described the novel method used to fill with clay the voids existing in a limestone cave under the dam. Plastic clay in the form of "sausages" or cylinders was fed into a casing pipe which had been carried up from the cavity 100 ft. or so and bedded in the masonry of the dam. The clay was driven by means of a pile-driver. The details are well described in Mr. Gowen's paper, and it is stated that a total of 66 951 lb. of clay was driven, apparently completely filling the cavity, as evidenced by the rising of the clay in a tell-tale pipe outside of the dam structure. In the speaker's opinion the method thus described could be used in many cases where the problem is merely to fill voids with a water-tight material and where it is not necessary to use material that will solidify like cement.

Mr. Smith. J. Waldo Smith,† M. Am. Soc. C. E.—This paper is a creditable record of many years of work under greatly varying conditions. The widely diversified aqueduct work provided an opportunity for the development of new ideas, and the 35 miles of pressure tunnel offered a much better opportunity than has before presented itself for the further development and perfecting of grouting methods. Due to the great number of men engaged on it and the variety of ideas that were presented, it is safe to say that more has been done to develop and put on record methods that will be useful in the future to those undertaking such work than ever before.

It is part of every one's duty to place in the archives of the Society records of methods that have been developed, for the benefit of others coming after or which will help the wayfarer looking for assistance along the road. Mr. Ridgway has stated that he hoped the speaker would suggest other papers. He has done so; but due to the war and perhaps also to the fact (which should be a matter for congratulation) that in most cases the men best suited to write these papers have gone on to better positions before their work was finished and before they had time to do so, the proposed papers have not been prepared.

The speaker still hopes that some of the men, although they are no longer connected with the work, will undertake to present a series of papers which will cover all the special features of the Catskill Aqueduct.

* *Transactions*, Am. Soc. C. E., Vol. XLIII, p. 469.

† New York City.

Mr. Smith.

The one that he wants to see more than any other is a comprehensive paper on the pressure tunnels, because the pressure tunnels, the grouting of which is so fully described in this paper, were among the principal features of this work.

If the speaker had undertaken to have a number of the engineers submit the data and had himself prepared this paper, he is sure he would have been very unhappy. He could not have done it as well as they have, and it is much better for those who have been close to the work and who have really done the work, to obtain whatever glory or credit or publicity may come to them through the presentation of such a paper as this.

The authors have said that this paper was prepared at the speaker's suggestion. Well, such suggestions are part of his religion. He believes that a man in the position he has been in owes it to his associates (there have been no assistants on this job) to see that they have a chance to develop, and to help them onward and upward. It is the duty of all the members of the Society who are in executive positions to do what they can to develop the younger men, to allow them to accept responsibility, or to force it on them. To place such responsibility brings results which would be beneficial to any project.

Mr. White.

LAZARUS WHITE,* ASSOC. M. AM. SOC. C. E.—This paper is so thorough and covers the subject so well that it is difficult to enlarge upon it. There is one impression which the authors did not intend to convey, but might be obtained due to the great emphasis on the grouting operations; that is, that the water-tightness of the tunnels was due almost entirely to the grouting, and that the concrete tunnel lining itself is of minor importance. This, in the opinion of the speaker, would be unfortunate, for, as Mr. Ridgway remarked, the tunnel lining itself is of primary importance and without a thoroughly good lining it would be hopeless to secure water-tightness for effective grouting. Those who examined the tunnels will bear witness to the fact that the lining was first-class with very few visible defects. To get good lining, every care was taken in leading the water off with drip-pans and grout pipes, as the authors describe. This prevented damage to the lining, allowing the concrete to set while it was entirely relieved of water pressure and water percolation. The same drip-pans and grout pipes which primarily served to lead off the water and protect the lining were the instruments for the subsequent grouting.

Had the vent pipes been blocked, the lining itself would be found to be very tight without the grouting. In one instance this was done, and the lining withstood a pressure of 135 lb. per sq. in. without leakage. This was described by the authors. The grouting, in the opinion of the speaker, was primarily designed to back up the lining, and to transfer the internal pressure through the concrete and grout to the rock backing.

* New York City.

Mr. White. It is the rock in pressure tunnels which, after all, carries the pressure, and it must necessarily carry it. In cases where sections of the tunnel lining failed, it was due to the fact that the rock backing was unable to carry the heavy internal pressure. On the Rondout Tunnel there were heavy layers of limestone between which were layers of greasy clay, and when the internal pressure was applied, the strata moved, cracking the lining. These stretches were repaired by putting in steel lining capable of withstanding the internal pressure without the aid of the rock.

As the authors have stated, there were people who predicted that the lining would fail in very numerous cases, and favored the use of a continuous steel lining to take up the internal pressure independently of the rock. It was decided that this would be too expensive, and it would be cheaper to test the tunnels hydrostatically and repair the weak spots in places where that was necessary. This was done and resulted in great economy.

It is to be noted that the grouting operations at the end of the work were quite different from those at the beginning, and much simpler. An elaborate arrangement of grout pipe, drip-pans, cut-off walls, collecting pipes, etc., which were at first shown in the design, were later dispensed with. The grouting methods which were subsequently used in the aqueduct were the result of a great deal of experience and developed from many years of work.

The impression might be given from the statement by the authors on page 1037 that the grouting behind the pneumatic caissons was responsible for their tightness when the air was taken off. The sealing of these caissons was accomplished by the simple expedient of dropping them on a bench of concrete so that the cutting edges compressed a heavy wad of oakum. Immediately after this the air was withdrawn, and the caissons were very dry. The grouting subsequently done behind the caissons was in the nature of backing them up and making more permanent the sealing accomplished by the oakum.

Mr. Hogan. JOHN P. HOGAN,* M. AM. SOC. C. E.—This paper is so complete in itself that there is very little that can be added to it. The only thing that any one can do in discussing it is to attempt to emphasize or bring out more strongly some of the points covered.

Of the points that the speaker would like to emphasize is one which Mr. White also has made, that in order to be successful grouting must be simple. Complicated systems of connecting pipes and elbows, leading a large quantity of water to a given point, and attempts to grout a large area during one operation, never succeed. Straight pipes and small drip-pans are needed. A small drip-pan is necessary for two reasons: first, in order that it may be grouted successfully, and,

* New York City.

second, to avoid bringing too large an area of the tunnel lining under pressure. The latter requirement became very important in high-pressure grouting, particularly in the Hudson River Siphon, where a grouting pressure of 700 lb. per sq. in. was used. In some cases on that work where the lining ruptured, there was evidence that the drip-pans were too large, and too large areas of the tunnel lining were exposed to the high-pressure grouting. Mr. Hogan.

The statement is made by the authors that the purpose of low-pressure grouting was: "(*a*) primarily to fill the void spaces between the lining and the rock, particularly above the arch, and, at the same time, to form a blanket over the construction joints in the arch; (*b*) to fill the voids in the dry packing where the latter was used; and (*c*) to fill any porous or honey-combed spots in the concrete." If anybody has had any success in filling porous or honey-combed spots in concrete with grout, the speaker would like to know about it, because, for about six weeks, experiments were made in the Rondout Siphon to impregnate leaky concrete with grout. The Board provided for this purpose a special grouting pad 2 ft. square, and consistent and persistent efforts were made to use it, with a total net result of loss of time and loss of money. The attempt to grout leaky concrete with this pad was like trying to use an irresistible force against an immovable resistance.

The speaker merely mentions this because the authors have carefully avoided any further mention of it in the paper. One does not get grout in place anywhere unless one has circulation. The simplest form is the grout pipe and the vent pipe; when you get grout out of the vent pipe, you know the intermediate space is filled. In the same way in filling grout seams, wherever there was any interconnection and circulation through the seams it was possible to get grout into the seams; but, in general, very little progress was made in attempting to grout the seams in the rock unless there were such interconnections.

The provision of sufficient vent pipes for circulation and for getting rid of surplus water and air also enables you to see what you are doing and what you are accomplishing.

It has been correctly stated that the lining and not the grouting was the primary cause of the tightness of the tunnel. The important thing in placing a tight lining is to prevent water pressure on the concrete while it is setting. It is necessary therefore to lead water through the concrete to prevent the accumulation of pressure, and it is necessary in some way to fill the void which existed for the purpose of collecting water. If it were not for the sake of permanency, the pipes leading through the concrete for the purpose of collecting water might be closed with an iron cap, or even possibly with a wooden plug. The grout forced in through these pipes, however, in addition to stopping permanently the inflow and plugging the pipe, helps to back up the lining over the area which the drip-pan covers.

Mr. Hogan.

In grouting on a large scale, special provision must be made for carrying the grouting pipes through the forms, particularly when steel forms are used. This was done on the Catskill Aqueduct by threading holes through the forms, and by leaving couplings on the ends of pipes, so that connections could be made to them readily.

In grouting large spaces, such as existed in the dry packing back of the steel shell on the Rondout incline, special measures are necessary. In the incline, at the time the concreting was started, there was an inflow of 1 200 gal. per min. of water within a stretch of about 180 ft. The placing of the invert was the most difficult operation on account of the necessity of caring for the water in the bottom, while the invert concrete was setting. This was successfully accomplished by laying a longitudinal 8-in. riveted steel pipe with 6-in. Y-branches. After the invert was placed, the steel arch ribs and the steel shingle plates were erected on it. The dry packing and the placing of the concrete were carried on without any difficulty. Wherever there was a heavy flow from the rock a hole was drilled back into that seam, and a deep-seated pipe was caulked back into this hole so that any water under pressure might be led readily through the lining and allowed to flow freely during the lining process and during the grouting of the space outside of the shell.

The space to be grouted in the dry packing was very large, averaging about 18 in. in diameter, with a radius of about 11 ft. The speaker does not remember how much grout was used in that shell, but perhaps Mr. Freeman will supply that information.*

After the lining had been placed and the water led through it by means of these deep-seated pipes, or allowed to drain through the dry packing down into the steel pipe in the invert, there were really two stages to the process of grouting—filling the dry packing, and shutting off the water. The object was to have a still lake of water into which the grout could be forced under low pressure. The grouting went on for six days; and so carefully was the high-pressure water controlled through the deep-seated grout pipes that there was no flow whatsoever in this lake of water in the dry packing.

In other cases, as much sand as possible was used in grouting the large spaces because it was less subject to churning action of the air, because it made a stronger grout, and because the shrinkage was less. In general, unless grouting small seams, it is advisable to use as much sand as the mix will carry. The quantity is entirely a question of experiment, but, in general, about half sand and half cement can be used. In this case, however, for various reasons, no sand was used; but it is believed that an equally good and more economical result could have been obtained by using sand with the cement.

* Mr. Freeman stated that the total quantity of neat cement injected into the dry-packed section on the incline north of Shaft No. 4, Rondout Siphon, was 7 693 bags. As many as 1 200 bags were injected in one 8-hour shift.

Mr. Hogan.

The grouting was done from the bottom up, so that the grout was forced in with at least a 1-ft. head over the inlet pipe. If the grout had been put in at the top and allowed to settle through the water, the cement would have been washed away so that its setting would have been greatly retarded, if not entirely prevented. After the grout in the dry packing had set, the deep-seated pipes and the pipes in the invert were grouted under high pressure and the inward leakage reduced from more than 1 000 gal. per min. to less than 2 gal. per min.

In all these operations it was necessary, as has already been mentioned, to avoid excess of air and the blowing of air through the grout. In connection with other operations in the Rondout Tunnel, grout was cut out and was found to be very strong and dense, though somewhat stratified. There was not much separation of the sand from the cement, and the weight of some of the samples cut out was as high as 118 lb. per cu. ft., compared to about 145 lb. for concrete.

Certain breaks in the lining of the tunnel were repaired by means of a steel shell made with 15-in. channels. As Mr. White says, the breaks were due to adjustment in the rock. There has always been a question in the mind of the speaker whether a number of those breaks could not have been repaired by grouting operations alone, without using the steel shell. However, it might have been necessary to put the tunnel under pressure several times and grout it several times in order to accomplish that purpose. The uncertainty of this procedure was too great, because it appeared at that time that possibly the work in question might be a limiting factor in the use of the Catskill Aqueduct.

It would be interesting if some one familiar with the actual grouting operations could discuss the relative value of air-mixing and hand-mixing grout machines, and their respective uses. It is certain that there is a field for each. The Catskill Aqueduct was largely grouted by use of the air-mixing grout machine. However, in the Hudson River Tunnel, where the pressures were about 700 lb. per sq. in., ordinary plunger pumps were used with a suitable hand-mixing device attached. There are objections to the use of air-mixing grouting machines. The greatest objection, of course, is the quantity of air forced in with the charge, and the difficulty of getting rid of it.

The portion of the paper in regard to the grouting of the foundations of the Kensico and Ashokan Dams, and particularly the grouting of the foundations of the earth dikes, has introduced very interesting possibilities of improving the foundations of dams which have been constructed, and of which the foundations have proved to be faulty or are known to be faulty.

It did not seem to the speaker that the necessity for the high-pressure grouting is clear. The majority of the work was done at between 30- and 60-lb. pressure, and during this period the ground-water was allowed

Mr. Hogan. to flow through certain pipes to prevent the building up of back pressure. However, when it came to finally closing up a stretch, the active ground-water pressure in that stretch was often as high as 150 or 250 lb. per sq. in.; indeed, in the case of the Hudson River Siphon, it was as high as 500 lb. It was surprising how quickly that pressure built up the moment the pipes were closed, and it was to overcome this ground-water pressure that high-pressure grouting was necessary.

Mr. Donaldson. FRANCIS DONALDSON,* ESQ.—The speaker was with three of the Aqueduct contractors and has actually placed a lot of grout. Mr. Hogan stated, and Mr. White agreed with him, that grout did not have much to do with making a tunnel tight, but the speaker begs to differ.

The speaker worked on one job not many miles from New York City. It was dry rock, the concrete lining was excellent, and when it was finished and looked as dry as possible, it was not quite dry enough for the engineers, so that high-pressure grouting was required. For weeks and weeks a gang of men went up and down that tunnel with step ladders and jack-hammer drills plugging at every drop of water; wherever the least dripping from the roof occurred a hole was driven and grout pumped into it. When we got through with that tunnel, it was positively dusty.

The speaker was on several of the other jobs to which the authors refer and describe so well. In the Hudson Tunnel, we used grout at a higher pressure than was stated; this was necessary because the head outside the tunnel was 1 100 ft. and we had to force the water into the seams around the tunnel back into the crevices through which it came. It went back a great deal harder than it came in. We used a booster compressor up to the limit of our air pressures, and as we could not get enough pressure this way we pumped in water on top of the grout with a high-pressure Cameron pump. The pressure ran up to something like 1 000 lb. per sq. in., and broke out big chunks of the lining; it was good concrete, too, notwithstanding the authors' suggestion that it was a little weak in spots. We finally got the tunnel pretty tight.

At Shaft 4 on the City Tunnel (which was referred to in the paper, although it has not been discussed by any of the speakers), we drilled into a seam of sand. This sand bed was cut by one of the sump holes and a strong stream of water came up through the hole, carrying with it sand in good-sized grains. We plugged it with a tapered wooden plug, and then, because the stream had amounted to some 200 gal. per min., we decided to grout it. Having made this decision, we kept grouting this seam for about one month, but found that the sand prevented the grout from flowing into any of the holes in any considerable quantity. However, as soon as one hole refused we drilled another and

* New York City.

kept drilling and grouting until the shaft bottom looked like a colander. There must have been several hundred holes in it. Mr. Donaldson.

When we could not get any more grout in we went on sinking and passed through the sand seam without much difficulty. We found that, although the grout had not permeated the sand, it had compacted it so that it resembled soft sandstone and all through the seam we found balls of grout ranging from the size of a man's fist to the size of his head. The leakage into the shaft, which came in through one hole—we did not know how much it would have amounted to if additional holes had been drilled—was cut from 200 to 20 or 30 gal. per min. This shows that grout can be used in sand under certain conditions; but no matter how thin it may be, grout will not permeate sand.

This discussion brings to mind two shafts which the speaker sank in West Virginia before he became connected with the Aqueduct work. Each shaft was about 275 ft. deep and it took two years to sink them. We had to pump about 2 500 gal. per min., and it required nearly 1 000 boiler h. p. all the time. The rock seams were open, and if we had known enough to grout them we could have saved much money and time.

When the shaft reached the seam through which the main flow came in, we found that it carried with it fine coke. Evidently, the particles floated into crevices in the rock in the banks of the river farther up stream, because still farther up the river there were a great many coke ovens, and after every heavy rain coke would be washed in. The biggest seam in the shaft was horizontal; it must have been 4 or 5 in. wide and ran nearly full of water.

One evening, going over to the shaft—something had happened to the pumps—the speaker met a darky coming away. He was carrying a good-sized catfish. The speaker said, "Sam, where did you get that fish?" And the darky replied, "Lord, boss, that came through the big crack in the shaft".

WALDO C. BRIGGS,* M. AM. SOC. C. E.—The speaker's experience with grouting is confined to a soft ground tunnel which is a part of the Dual Subway System located under Flatbush Avenue, Brooklyn, extending from Prospect Park Plaza to Empire Boulevard. This section is a twin tunnel constructed in a single excavation, about one-half having been driven by means of a shield and the other half by a timber method. Mr. Briggs.

With respect to stopping leaks, three different conditions were presented. Where the shield was started, the material penetrated was a clay carrying a great deal of water. The grouting operations were initiated in this section, and it was the intention to force in only sufficient grout to fill the void caused by the shell of the shield. The concrete behind the shield was placed in rings 31 in. wide by a pneumatic process. The concrete, due to the great quantity of water in the soil, was

* Brooklyn, N. Y.

Mr. Briggs.

porous; this condition, together with the large number of construction joints, produced a very wet tunnel. The result of the attempt to just fill the voids caused by the shell of the shield by means of the grout, so far as stopping leaks is concerned, was a complete failure.

A year or more after this section of tunnel had been completed and the grouting done as described, another attempt was made to stop the leaks by grouting. New holes were drilled through the lining just below the springing line through which grout was forced freely. For a certain distance the tunnel was made dry; but, inasmuch as grout is costly, a limit was set as to the amount of grout used, with the result that where the grouting was so limited, the tunnel is wet. The conclusion to be drawn from this is that porous concrete and construction joints in tunnel lining can be made water-tight by grouting, provided sufficient grout and pressure are used. In the case in question the pressure used was 80 lb. per sq. in.

Another condition, where the shield passed through what was evidently a terminal moraine, the material excavated consisted of boulders and gravel entirely free from any matrix. A section of tunnel at this point, about 100 ft. long, was also wet after the lining had been completed; and, although grout was used freely, the leaks were not entirely stopped, probably due to the fact that the voids in the formation were so extensive it was impossible to force the grout into the concrete.

The third condition was where the timber method of tunneling was followed and where the material penetrated was clean, sharp sand carrying a great quantity of water, the water again causing a somewhat porous concrete and a wet tunnel. Grout forced in through pipes located in the crown of each arch under a pressure of about 65 lb., cut off all water and left a bone-dry tunnel.

The speaker requested the foreman, Mr. Joseph Callahan, who had been in charge of the grouting operations on the work in question, to give him any information which experience had taught would be useful. The following notes were offered in response to this request:

"It is very important to have good hose and valves. The valves used should be cleaned thoroughly every morning or they will become clogged with grout and be useless. The hose and grout kettle should be washed out noon and night. A blow-off valve should be provided at the end of the hose so that if the grout gets blocked in the hose, it can be released. Only cement free from lumps and finely screened sand should be used. Coarse sand and lumpy cement will block the kettle and the hose and valves. When connections are made ready for grouting, try the air to see whether the hole is free. If the air passes slowly, try a thin batch with neat cement at high pressure. The grout pipe in the wall should be cleaned out with a rod. If a hole has been taking grout freely and stops suddenly, it indicates a block; perhaps a stone has fallen into the grout pipe. In such a case, let the grout come back into the kettle,

close the valve at the wall and open the exhaust valve; this should take stones with it. Mr. Briggs.

"All grout pipes should be cleaned at least 75 ft. ahead of the connection in order to release any water which may be behind the wall. As the grout shows ahead of the connection, plug the pipes with wooden plugs. When a hole is not finished at the end of a shift, blow in a little water; this will often keep the hole open until the next shift.

"Before connecting the air pipe to the kettle, blow air through pipe for dirt in the pipe will clog the valves in the kettle and cause trouble.

"Be sure that valves are screwed on tight and that there are no kinks in the hose. If a valve blows off or a hose 'busts', some one is liable to get hurt."

A. J. Sackett,* Assoc. M. Am. Soc. C. E.†—The speaker can add very little to this excellent paper, which covers the ground so thoroughly. Mr. Hogan in the course of his discussion brought out the fact that it is impossible to force grout into poor concrete. The speaker has found that this is true except when the concrete is placed in compressed air, in which case grout washed on the surface of the concrete will be carried through the concrete and fill up the voids thus preventing the escape of air from the tunnel and also decreasing the leakage into the tunnel when the pressure is removed. Experience gained from grouting the Moodna Siphon where 1½-in. pipes were used through the concrete lining shows that much better results can be obtained by using a larger pipe; 2-in. pipes were used on Section No. 63 of the City Tunnel, resulting in a better job of grouting and economy in time. Mr. Sackett.

When electric power is available, it is more economical to develop the compressed air by means of a small portable compressor at the grout tank than to transport the compressed air from a central plant through pipe lines.

In answer to the question as to why hand pumps were used in grouting on the Catskill Aqueduct, it has been the speaker's experience that grouting by hand pumps is a makeshift and only resorted to on small jobs and at places where power is not available or too expensive to obtain.

Concreting the 150-ft. forms on Section No. 63, which Mr. Sanborn has requested the speaker to describe, was a simple process and did not differ in any material way from the methods used to line the tunnel on other sections of the acqueduct. Sand and crushed stone were passed by gravity from bins at the shaft head to a measuring hopper, then through a 12-in. wrought-iron pipe to a 1-cu. yd. concrete mixer mounted at the foot of the shaft. The cement was mixed with water at the top of the shaft, to prevent dust, and dropped though the same pipe with the coarse aggregate. The mixed concrete was transported in 1-cu. yd., side-dump cars, in trains of 8 to 10 cars hauled by electric motors. The forms

* New York City.

† Now M. Am. Soc. C. E.

Mr. Sackett. were built of steel and mounted on trucks which traveled on the same track used by the material cars. The trains of concrete cars were hauled up an incline to the platform of the forms by an electric hoist. The side-wall form traveled in front of the arch form, the two being concreted at the same time. Cars were dumped on the platform, which was about 18 in. above the springing line of the tunnel, and the concrete was shoveled into the forms by hand.

Mr. Cohill. ANDREW A. COHILL,* M. AM. SOC. C. E. (by letter).—In the construction of two tunnels under the East River at 60th Street, known as Route 61, Broadway-Fourth Avenue Subway, there were conditions to contend with that were exceptional, especially the leakage. There was a water pressure exceeding 50 lb. per sq. in. The problem of taking care of the water under Blackwell's Island was a difficult one.

With C. M. Holland, M. Am. Soc. C. E., as Tunnel Engineer, and M. H. Freeman, M. Am. Soc. C. E., as Resident Engineer in direct supervision of the work, precisely the same methods as those described in this paper were used, and the results obtained were excellent. Approximately, 11 000 ft. of tunnel was grouted, of which 5 000 ft. has a cast-iron lining. The leakage before grouting was 800 to 900 gal. per min.; this was reduced, by grouting, to approximately 25 gal. per min.

The writer wishes to compliment the authors on the excellence of this interesting and valuable paper.

Mr. Mayell. A. J. MAYELL,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer was much interested in the grouting methods used on the water tunnels, as described by the authors, and especially in the use of grout of varying consistencies, and can testify that the methods are efficacious in stopping leaks not only in water tunnels but in the New York subways.

Similar methods were recently used with great success by M. H. Freeman, M. Am. Soc. C. E., at the Broadway Station of the Canal Street Crosstown branch of the Broadway-Fourth Avenue Subway where considerable leakage developed after construction was completed, and ground-water which had been lowered by pumping during construction regained its original elevation.

This station is entirely below mean high water, and was therefore enveloped in water-proofing consisting of two layers of brick laid in asphalt mastic. Where it passed under the Interborough Subway in Lafayette Street and the Centre Street Loop in Centre Street, the water-proofing, instead of being carried over the roof of the new structure, was lapped on to the water-proofing on the under side of the overhead structures. It is probable that a slight subsidence of the mastic together with pressure from the water head caused this water-proofing lap to open slightly and admit ground-water into the subway.

* New York City.

Before the ground-water had risen to its normal level, the station finish was placed and the subway put in operation, so that when the leakage developed the water was carried by the hollow tile and through air spaces a considerable distance from the points of entry and flowed across the platforms causing annoyance and inconvenience to passengers. Mr. Mayell.

It was decided to attempt to stop the leaks by grouting from the inside of the structure; holes were drilled through the interior walls in the general direction of the water-proofing lap, and grout was injected under pressures of from 30 to 70 lb. per sq. in. The total leakage at the start was about 160 gal. per min., most of it coming in under the two overhead structures. The grouting reduced the leakage to less than 1 gal. per min.

The grouting was done under difficult conditions. The station platforms and passageways from which grouting operations had to be carried on were crowded during rush hours and great care had to be taken to prevent accidents. Moreover, special precautions were necessary and constant vigilance had to be exercised to prevent the grout from filling the hollow tile, air spaces, lighting conduits, and drains. Pressures had to be kept fairly low to prevent damage to the structure and to the overhead structures.

The great force that may be exerted by grout under pressure is indicated by the fact that the Interborough Subway, which during the construction of the structure below it had settled from 1 to 3 in., was raised from 1 to 1½ in. by the grouting. This occurred after all the holes under the Interborough Subway had been grouted and the process of "squeezing" to complete the seal was in operation. The squeezing was done by a hand grout pump with a pressure gauge attached. The pressure generally used was between 50 and 60 lb. per sq. in., but on this occasion the grout was going in very slowly and the pressure was increased, as it was thought that the space between the two structures had been quite thoroughly grouted and that the grout could not exert pressure on any great area of the overhead subway bottom.

No damage was done to the overhead structure; on the contrary, the lifting eliminated the greater part of the depression in the inverts of the Interborough structure which the operating company had thought might affect the drainage of its tracks.

That the results obtained were so successful was due to the intimate knowledge which Mr. Freeman had of the action and effect of grout of different consistencies and his constant attention to this detail.

MILTON H. FREEMAN,* M. AM. SOC. C. E.—The authors of the paper deserve credit for presenting data of great value. Such data are most difficult to obtain as they involve many trials and experiments on work Mr. Freeman.

* Valhalla, N. Y.

Mr. Freeman.

of considerable magnitude. The following detail considerations are submitted as being of possible interest.

Placing and Protecting Grout Pipes.—Reference has been made to the necessity of a good concrete lining in order to make grouting a success in securing a water-tight tunnel, and it may be of interest to consider some particular features relative to the placing and protection of grout pipes as an aid in securing good concrete. The placing of pans and pipes subsequently to be grouted requires the utmost care and forethought; they should be placed with some method in mind for finally filling them with grout, not simply with the idea of taking care of incoming water. A careful record should be made showing what particular function each pipe serves at the rock end so that, later, grouting can be done intelligently. Pipes are sometimes disturbed by the placing of a heavy mass of concrete, and a most careful inspection of these pipes is necessary during concreting. All drain pipes, of necessity, have to be brought through the forms, and it is far better if the vent pipes are placed in this way so that they may be cleared of any concrete that may become lodged in them while the concrete is still soft. Pipes draining large leaks usually free themselves of any mortar that may work in from the concrete, but pipes set to drain small drips are easily clogged, and it is not an uncommon experience to find one that was placed to pick up a small drip perfectly dry, while the leak finds its way through the body of the concrete at some near-by point. A material aid in such cases is the washing out of the bottom of the drain pipe by inserting a small (½-in.) pipe connected to the water line, or air line if water is not available, after the manner of blowing out drill holes before loading in a rock heading. This must be done with extreme care after the concrete is from 1 to 2 ft. above the rock end of the pipe. This procedure has often saved pipes that started to clog at the rock end.

Shaft Ring Pans.—The ring pans in shafts, as described by the authors, have a double service: First, they furnish channels for grouting any shrinkage cracks between the concrete and the rock and possibly cracks in the rock itself; second, and probably their most positive function is to collect seepages that are not easily discernible, and consequently are not taken care of with individual pans on the wet sides of a dripping shaft, and which follow up behind the concrete until collected in the ring pan. Where these pans have been used, it is a most common occurrence to find the down drain pipes dripping after all the concrete has been placed. Since leaving the work on the Aqueduct the speaker has found in certain instances, where shaft lining has been placed without the use of these pans, that there is a greater tendency to leakage at horizontal joints. The pans are preventatives against such leaks.

It has been thought by some that it might be worth while first to grout these rings with thin grout under high pressure, to penetrate the

rock seams, and afterward blow them out and close them with thick grout. Mr. Freeman.

Displacing Water with Grout.—Recently, the speaker has had occasion to do some grouting where water had to be displaced by grout, and found that when the volume of cement to be injected is comparatively small and the necessary grouting pressures not excessive (60 to 80 lb.) the hand pump has proved to be of excellent service, as it is under instant control, wholly eliminates the ill effects of the after-blast of air, and displaces the water by grout without disturbing and mixing the two. From 100 to 150 bags of cement can be injected with the hand pump per 8-hour shift, under favorable conditions. Grouting to displace water with an air-discharging grout tank is most difficult to accomplish without the formation of considerable laitance. Shutting off the tank pressure when the hose kicks or when the tank gauge pressure drops is of value, but when this phenomenon takes place, a charge of air has already gone through the hose, to stir up the grout with the overlying water. Keeping the grouting pressure as low as possible is a worth-while precaution, even at the expense of clogging the hose once in a while.

Volume of Set Grout in Place.—The question of the ratio between the volume of mixed grout and the volume of set grout in place is often required, sometimes as a payment quantity. The contracts of the Board of Water Supply very wisely avoided this, as it has been found that there is no fixed, definite ratio. Not only does the volume vary with the quantity of water and the quantity and kind of sand used, but the degree to which the grout mass is shaken in the process of placing. Experiments on small quantities indicate that, due to the latter cause alone, a variation of 20% may be found. If necessary to determine this ratio, experiments involving the particular kind and quantity of sand used and the quantity of water utilized for mixing will probably give the most reliable data.

Grouting Overhead Closures.—One feature of grouting which may be of interest is the method of making overhead closures where the surplus water from the grout is trapped, that is, cannot be disposed of by increasing the grouting pressure. Concrete structures are often built up under other structures, where it is essential to secure a good bearing, possibly a joint that will be water-tight. A concrete arch placed inside a steel or iron lining is another illustration.

Certain features in regard to this kind of grouting have been worked out as follows:

1.—The thicker the grout the less surplus water will be thrown off.
2.—Practically all this surplus water is thrown off and pools form on the top of the grout within one hour after placing.

Mr. Freeman.

3.—If sand is used, the presence of a small quantity of loam (as little as 5%) increases noticeably the amount of laitance at the top.

4.—A second, third or possibly a fourth grouting may be necessary finally to fill the space occupied by the surplus water from the grout ejected previously.

5.—Vent pipes should be set to take advantage of any small summits; if the overhead structure is of concrete, summits may be chipped out. Arch or roof concrete forms often sag when concrete is placed on them, but the vent pipes should not be allowed to sag with the forms.

If all pipes are cleaned out as soon as the grout has partly set, the same pipes can be used for subsequent groutings. This necessitates individual vent pipes to each summit. A second grouting usually leaves only a very small space unfilled, but sometimes grout can be injected at a third or fourth trial. Neat cement grout is commonly used after the first grouting. Higher pressures can be used with advantage as the space fills up, if the structures themselves are strong enough to withstand such pressures. The foregoing, of course, applies only to places where it is essential to obtain a complete contact between the two structures.

Grouting Undisturbed Sand.—Several attempts to grout undisturbed sand have come under the speaker's notice, but all such attempts were ineffectual, even though thin grout and high pressures were used. A little cement can sometimes be injected into gravel that contains no fine sand as a filling material.

Mr. Riker.

C. L. RIKER, JR.,* ASSOC. M. AM. SOC. C. E.—High-pressure grouting operations were resorted to on the lining of about 1 200 ft. of the Catskill Aqueduct in the section south of Twenty-fifth Street, New York City, following the development of outward leaks through numerous small cracks which opened in the concrete lining during the initial hydraulic test of this section. These cracks were due to the compression or shifting of the soft seamy rock through which this section of the tunnel passed.

This section had previously been grouted by the use of both low and high pressures, but numerous hair cracks in the lining indicated that the original high-pressure grouting had not penetrated the minute seams of the rocks a sufficient distance or thoroughly sealed and formed an unyielding backing to the lining. Ground-water flowed freely from many of these cracks. It was necessary, of course, to stop this flow entirely prior to commencing grouting operations. These leaks were

* Brooklyn, N. Y.

effectively stopped by chipping out a groove along the line of the crack and caulking the groove with lead wire. Mr. Riker.

Threaded pipes, 1¼ in. in diameter, were rolled tightly with cotton drill and driven into 2¼-in. holes bored in the concrete lining. This formed an entirely satisfactory and tight joint between the pipe and the tunnel lining.

In regrouting this section, 9 500 ft. of 2¼-in. hole, or a little less than 8 ft. of hole per foot of tunnel, was driven, and 2 400 connections were made to these holes, or 2 connections per foot of tunnel treated. More than one connection was made to many of the pipes, and some were only used for venting purposes. About 44 000 cu. ft. of very thin liquid grout was forced through these connections, using air pressure at from 250 to 350 lb. per sq. in. at the displacement tank.

Generally speaking, apparently the grout was effectively prevented from re-entering the tunnel. However, a peculiar substance incident to the grouting accumulated within the tunnel. A heavy grayish custard-like mass was formed, which, when quiescent, became almost as hard as cheese; when agitated it became soft and liquid, and was carried in solution by a sluggish flow of water in the invert. A settling basin was formed on a slope down stream from the grouting operations, and about 800 cu. yd. of this soft waste matter accumulated as a result of 45 000 cu. ft. of liquid grouting.

A considerable amount of solidified droppings accumulated adjacent to the grout tanks, caused by spillage, venting, and blowing out the grout hose. Apparently, most of the grout so wasted solidified adjacent to the grout machine even though dropped into the slowly flowing water in the invert as well as on the lower quarters of the tunnel.

It is hard to account for the enormous quantity of this custard-like material, and it would be interesting to know whether the grouting process generally results in similar waste products, and, if so, of what this waste material consists.

BENJAMIN A. HOWES,* ASSOC. M. AM. SOC. C. E.†—An important point as to the fine grinding of cement is involved. Theoretically, as the authors intimate, it would seem that very finely ground cement would percolate more readily into the finer cracks and crevices as grout. Likewise, it would seem that if the cement were ground extremely fine, it could be carried into the interstices of sand and gravel as grout to consolidate them in place. The authors' statement indicates that experience shows this to be impossible and that standard fineness has been found to be more practical. Mr. Howes.

The mechanical features of setting and hardening explain this seeming clash between theory and practice. The finest particles are hydrated by the mixing water almost immediately, because the water reaches the entire mass at once. Particles of appreciable size are reached by the

* New York City.

† Now M. Am. Soc. C. E.

Mr. Howes.

water only on the exterior surface, and hydration proceeds by the attack of successive layers and to some extent by percolation of water into crevices of the particles. Ordinarily, the still coarser particles are hydrated on their exterior surfaces only, and these coarser particles with some 10 or 15% of inert constituents often comprise 40% of the cement. They act as reserves or factors of safety and will hydrate in time if needed to consolidate the mass.

Therefore, for grouting it is essential that a large part of the cement be ground so coarsely that it will not hydrate until it has reached its final resting place and will then by slow hydration consolidate the fluid that has been the carrier.

When a porous tunnel lining is under air pressure, grout will carry the coarse particles into the pores to some extent and there they will hydrate and stop the flow of air or water, but this only in very small degree fills and consolidates the total porosity. There is one place where these reserves of coarse particles demonstrate their office very plainly—in the case of small cracks in a concrete wall retaining water. Sometimes the cement reserves seal the crack in place and sometimes percolating water brings dissolved cement to the surface, where evaporation condenses it to seal the crack.

The speaker has found these unhydrated coarse particles of cement in hydraulic structures years after construction. In one case a tunnel lining, in another, a dam which had been in use 4 or 5 years showed unhydrated particles of cement from $\frac{1}{1000}$ in. to $\frac{1}{2000}$ in. in diameter. These particles had the characteristic cellular structure of Portland cement clinker. Hydration had taken place around the surface of the particles, and the interiors of such particles appeared to be ready to hydrate if water was introduced through a crack or otherwise.

Mr. Belzner.

THEODORE BELZNER,* ASSOC. AM. SOC. C. E. (by letter).—Milton H. Freeman, M. Am. Soc. C. E., states that "several attempts to grout undisturbed sand have come under the speaker's notice, but all such attempts were ineffectual."

It might be of interest to state that the writer recalls a few experiments made some years ago, during the earlier construction of the subway in the lower section of New York City, by forcing grout into undisturbed sand under pressure. When the material into which the grout had been injected was excavated, it was found that the cement had not been distributed uniformly. The material was lumpy and of no value whatever.

Mr. Zipser.

M. E. ZIPSER,† ASSOC. M. AM. SOC. C. E. (by letter).—It is very gratifying to the authors that the paper has been discussed by those so well qualified to give expert opinion on the subject.

* Brooklyn, N. Y.
† New York City.

Mr. Zipser.

Mr. Ridgway's point that a good concrete tunnel lining is essential in order to accomplish successful results in subsequent grouting, is very important. This matter is also given emphasis by Mr. Briggs' discussion of the case where costly grouting had to be resorted to in order to stop the leaks in a tunnel lining the concrete in which was porous, due, apparently, to lack of proper provision to keep the water away from the concrete until the latter had set.

Mr. Smith's remarks are very much appreciated by the authors. All who had the good fortune to be associated with Mr. Smith in the building of the Catskill Aqueduct know that the guiding genius and inspiring personality of the Chief Engineer stimulated every one to put forth his best effort.

Mr. White very properly calls attention to the fact that it was not the grouting alone that made the pressure tunnels water-tight, but that the concrete lining itself was, to a large extent, responsible for the tightness. Just to what degree the grouting and the lining each contributed to the results obtained, is difficult to state. When the plans were being prepared, it was thought that it would be possible to plug all the cracks and crevices in the rock and impregnate any porous rock surrounding the tunnel with grout, and that the concrete lining after having served the purpose of a bulkhead for the grouting would provide a smooth coating to produce a high coefficient of flow. In actual practice, however, it was found to be impracticable and of no advantage to attempt to force grout into all the fine seams in the rock. The results aimed at could be obtained by the simple but effectual methods developed during the progress of the work.

Mr. Hogan questions a statement of the authors, namely, that one of the purposes of the low-pressure grouting in the pressure tunnels was "to fill any porous or honey-combed spots in the concrete." What the authors had in mind in this connection was the filling with grout of any porous concrete in the top of the arch, where the consistency of the concrete when placed was relatively dry, and there was no opportunity for working it. For this purpose the grout was very effective in making the arch concrete dense and solid.

Mr. Freeman, in his discussion, brings out several important points in connection with the details of grouting. Mr. Freeman's wide experience and signal success in grouting work under varying conditions makes his contribution an especially valuable one.

In conclusion, the authors wish to thank all who have discussed the paper. Their comments and suggestions, and their accounts of experience on other work, will be of great value to any one who may be called on to engage in grouting operations.

Paper No. 1448

A NOVEL METHOD OF REPAIRING A SWING BRIDGE*

By Herbert C. Keith, M. Am. Soc. C. E.

With Discussion by Messrs. T. Kennard Thomson, Guy Pinner, Shortridge Hardesty, and James B. French.

Synopsis.

In the course of the regular inspection of the bridges of The Connecticut Company in 1912, the bottom chords of the swing span of the Washington Bridge over the Housatonic River were found to be in a dangerous condition because of the great loss of section by corrosion, due to the street drainage having been discharged upon the chords for years.

This bridge carries a highway with a single electric railway track, and being on the direct route from New York to Boston, the traffic is moderately heavy. There is no other bridge within seven miles to which this traffic could be diverted, and as the Housatonic at this point is a navigable stream, any material interruption either to navigation or highway and railway travel during reconstruction was prohibited.

This paper describes the methods used to renew the chords, with a very material saving of time and money, without impeding traffic. A system of temporary adjustable timber substitute members was devised to carry the bottom chord stresses while the permanent chords were being renewed, allowing the free use of the bridge for half the width

* Presented at the meeting of April 7th, 1920.

of the roadway at all times, and also permitting the span to be opened as required for river traffic.

Location.

Washington Bridge, connecting the Towns of Stratford and Milford, Conn., crosses the Housatonic River about 1½ miles above its mouth, and carries the main highway between Bridgeport and New Haven. At this point, the electric railway of The Connecticut Company has a single track in the highway, though the line is double-tracked for most of its length.

Original Construction.

The bridge was built in 1893 by Dean and Westbrook, as a highway bridge, for Fairfield and New Haven Counties, the steel having been fabricated by the Berlin Iron Bridge Company. This structure consists of a 203-ft. swing span with a 232-ft. fixed span at each end. The fixed spans have through pin-connected triangular trusses with curved top chords, each span with eight 29-ft. panels subdivided into sixteen floor panels of 14 ft. 6 in.

The swing span has through pin-connected trusses, Fig. 1, with an 18-ft. rectangular pivot panel flanked at each end by three triangular panels of 30 ft. 10 in., subdivided into six floor panels 15 ft. 5 in. long. The top chord of each arm of this span is curved, with a height varying from 20 to 33 ft. This swing span is entirely center-bearing, but has a turn-table with six wheels running on a circular track to provide for unbalanced load. The original bottom chords were 7-in. channels, latticed, 13¾ in. back to back, with splices near the main panel points. In the pivot panel were two additional channels between the outer ones, the latter being continuous with those of the remainder of the chord.

In all the spans the trusses are 19 ft. 6 in. on centers, the highway being carried between the trusses by 24-in. plate-girder floor-beams hung below the chords by loop hangers passing around the pins and down to tie-plates under the bottom flanges. The plank floor is supported by I-beam and channel stringers resting on cast-iron chairs on top of the floor-beams.

One of the designers of this bridge said, many years later (after having had extensive experience in bridge construction), that he doubted if there was a pound of surplus material in the original bridge in excess of that required to meet the specifications under which it was designed.

Earlier Repairs and Alterations.

Originally there was no track on the bridge, but one was laid later, its center line in 1913 being 3 ft. 11 in. south of the center line between trusses, as seen in Fig. 2.

The bridge has been strengthened or extensively repaired or altered several times, one of the more recent changes being the addition of a 4-ft. sidewalk on brackets outside of the north trusses. At the same time, The Connecticut Company renewed its track stringers, increasing their capacity, and cover-plates were added on both flanges of the floor-beams; additional floor-beam hangers were put on, and some repairs were made to the bottom chords of the main trusses. This work was required not only to provide for increased loads, but because of serious corrosion found on many parts of the bridge.

Condition in 1912.

Examination of this structure in the course of a general inspection of the bridges of The Connecticut Company in the fall of 1912 revealed the fact that serious corrosion had taken place in the bottom chords of the swing span. Although the bottom chords of the fixed span (being of eye-bars) had suffered no material loss, the discharge of drainage from the roadway through slots in the under side of the wheel guards had been very destructive to the latticed channel chords of the trusses of the swing span. The chords of both trusses of this span were in such condition for nearly the whole length that their immediate renewal was necessary, or else the use of the bridge would have had to be discontinued. As indicated by Fig. 3, in several places, the top or bottom flange of a channel was nearly or entirely gone, and at other places large holes were rusted through the web. Corrosion was general for the whole length of both trusses, but was greatest near the pivot pier, and the inner channels had suffered more than the outer ones.

Some of the pin-holes had been enlarged by rust or badly distorted by overstrain (see Fig. 4). Unfortunately, no satisfactory photograph was obtained of the worst case of such enlargement, where rust had enlarged the pin-hole more than 1 in. beyond its normal lines.

These facts made it evident that the unit strains on the reduced chord sections, due to the dead load when the bridge was swinging, far exceeded any possible live load unit strains, and the chief danger of failure was by "breaking its back" when swinging rather than by weakness for carrying traffic.

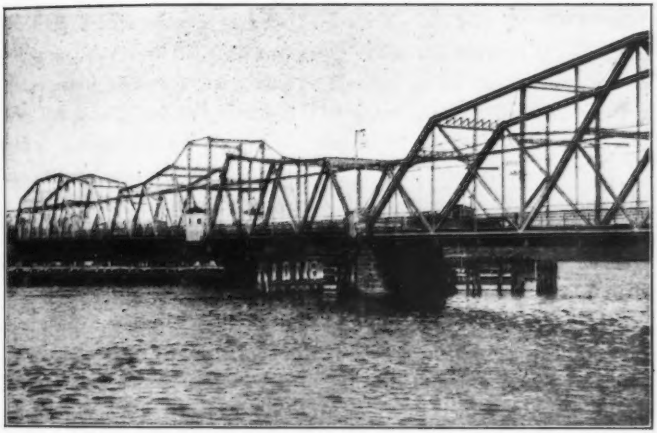

FIG. 1.—GENERAL VIEW OF WASHINGTON BRIDGE OVER HOUSATONIC RIVER.

FIG. 2.—EAST PORTAL OF WASHINGTON BRIDGE OVER HOUSATONIC RIVER.

Factors Affecting the Method of Repair.

The first method of procedure to suggest itself was to construct a temporary bridge with a jack-knife draw on one side of the present bridge, and to divert the traffic thereto. Then the draw of Washington Bridge could be swung open and be blocked up on the fender pier to allow the renewal of the chords. The great expense involved in this method quickly forced the consideration of other possibilities—and quasi-possibilities.

There is no bridge or ferry across the Housatonic River below the Washington Bridge, but the main line of the New York, New Haven and Hartford Railroad has a four-track bridge over the river about ¼ mile up stream. The location and construction of this bridge and its approaches, however, are not such as to allow easy or economical diversion of highway or trolley traffic to it. The nearest other public means of conveyance across the river is 7 miles distant; to divert traffic to that route would have added about 12 miles to the 17 miles by direct route from Bridgeport to New Haven.

Both passenger and merchandise traffic across the Washington Bridge is moderately heavy on the electric railway and also on the highway, as the bridge is on the most direct route between Bridgeport and New Haven and between New York and Boston. The inconvenience and expense that would have been caused by the interruption of traffic would have been great. Some of the traffic would have been discontinued or sent by railroad, but most of it would have been diverted to the crossing 7 miles up the river, with an average increased haul of about 12 miles.

The river traffic is lighter, but the Federal Government gives such attention to the maintenance of its water traffic that it is more practicable to stop entirely thousands of travelers on a highway or railway over a navigable stream rather than prevent for a single hour the passage of a yacht, or a tug with a scow, across the line of such highway or railway. It was learned, however, that Nature does each winter what the Government prohibits man from doing—closes the river to navigation for about three months. Records kept for several years show that the ice became so thick as to prevent navigation from December or January to March or April of each winter for which records were available. It was thought that the War Department might be persuaded to allow piles to be driven through the ice, provided that such a

man-built barrier were not allowed to remain to interfere with theoretical open navigation longer than the ice presented its prohibition to actual navigation. However, uncertainty of obtaining such permission, as well as the cost of this method of making the repairs, emphasized the desirability of further study of other methods.

It may be observed from Fig. 5 that though the swing span has six floor-panels at each end, yet, structurally, it has only three panels in each arm, each truss panel having its bottom chord divided into two parts corresponding in length with the floor-panels and, of course, having equal stress. As only about one-third of the deflection of the draw when swinging was taken up by the end lifts, nearly all the dead load was carried by the trusses to the center bearing even with the bridge closed, very little of this dead load being supported at the ends. This resulted in a constant compressive strain in the whole length of the bottom chords except the end panels, whether the bridge was swinging free or was closed and carrying the maximum live load. Only a small tensile stress was possible even in the end panels. The plans were examined, and careful inspection was made of the structure itself to ascertain whether careless erection or the numerous repairs and strengthenings might have changed conditions from those shown on the plans. It was found that there were small spaces on each of the main pins where jaws of compression members could obtain bearings.

Consideration of these facts led to the adoption of a plan for carrying the bottom chord strains by temporary substitutes while the chords were being renewed, and study of the problem brought conviction that this was not only feasible but a surprisingly economical solution. It avoided the cost of falsework and of constructing a temporary crossing for a detour.

Stress Requirements and Assumptions.

It was assumed that raising the ends of the swing span relieved each truss of that portion of the dead load which was concentrated at the end panel points, L_0, leaving the remaining dead load carried as if the bridge were swinging free. The live load was considered as carried by a continuous truss on three supports. With these assumptions, if (*a*), the railway traffic were stopped during the progress of the work; (*b*), the sidewalk were removed; and (*c*), the highway traffic were confined at all times to the half-width of the bridge away from the truss on which the work was being done, the maximum stresses in the bottom

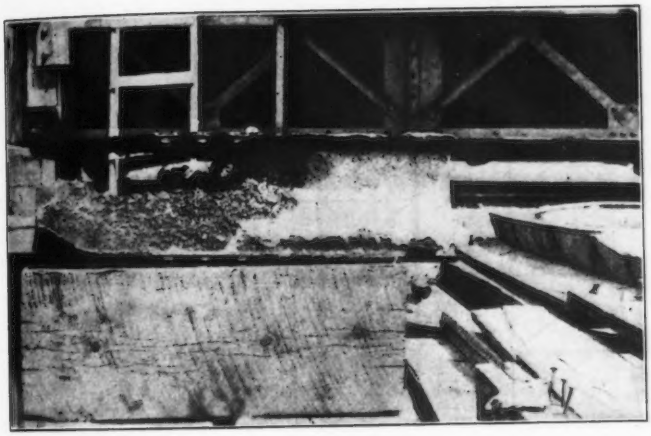

FIG. 3.—INNER CHANNEL OF BOTTOM CHORD OF PIVOT PANEL, SOUTH TRUSS.

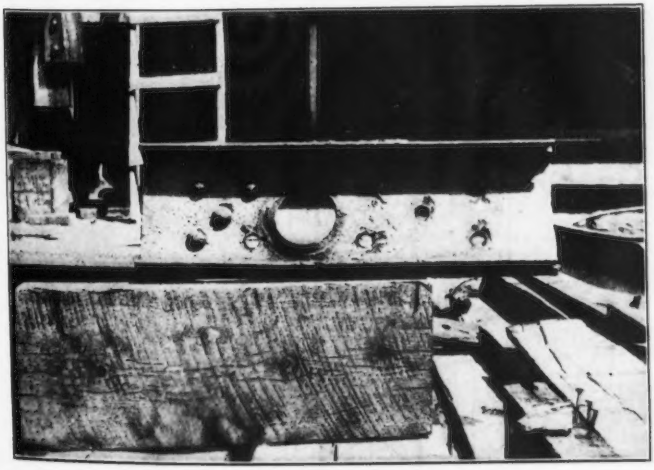

FIG. 4.—INNER CHANNEL OF BOTTOM CHORD OF SOUTH TRUSS AT L_0.

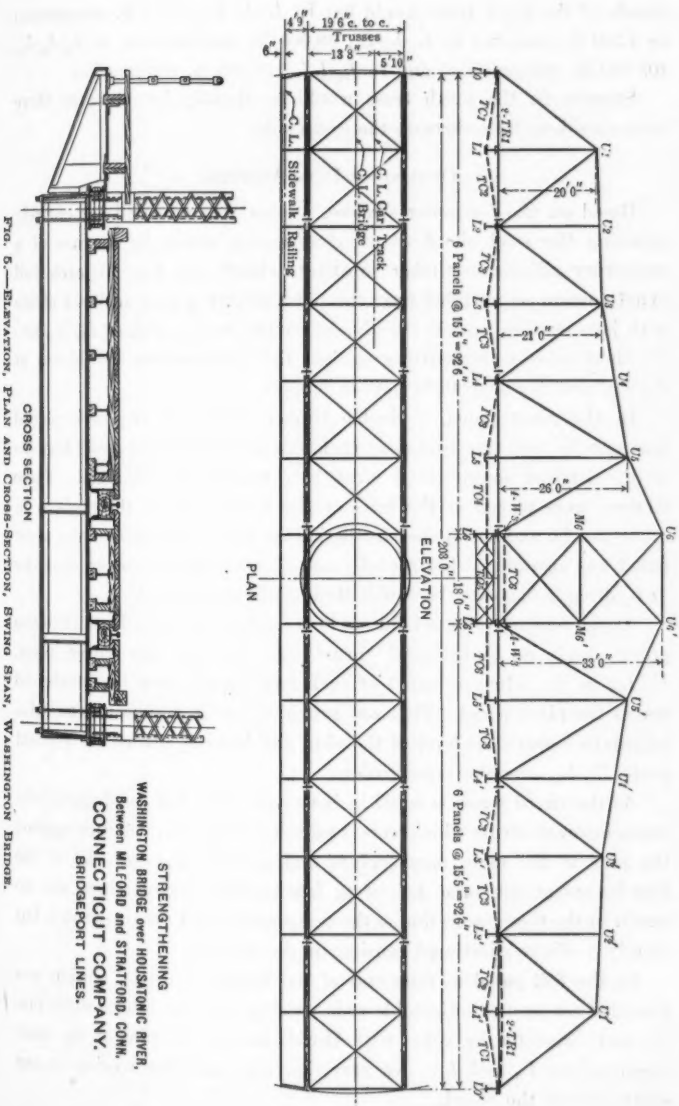

FIG. 5.—ELEVATION, PLAN AND CROSS-SECTION, SWING SPAN, WASHINGTON BRIDGE.

chords of the north truss would be: In L_0-L_1-L_2, 6 600 lb. compression or 4 300 lb. tension; in L_2-L_3-L_4, 49 000 lb. compression; in L_4-L_5-L_6, 105 000 lb. compression, and in L_6-L_6', 118 000 lb. compression.

Stresses in the south truss would be slightly less, because there were no sidewalk brackets on the south side.

Outline of Plan Adopted.

Based on the foregoing stresses, a plan was prepared for entirely relieving the steel chord of all compressive strain by the use of a temporary adjustable timber substitute chord (see Fig. 5), each full panel (except as modified near the pivot panel) having inclined struts with jaws bearing against the pins at the main panel points, L_0, L_2, and L_4, their other ends abutting against the intermediate floor-beams at L_1, L_3, and L_5, near their bottom flanges.

In the pivot panel, a double timber strut was required, placed horizontally with one timber at each side of the latticed strut, because of the latticed longitudinal strut between the cross-girders. These timbers were placed at the level of the lower ends of the timbers in other panels, and the timber in the half-panel at each side of the pivot panel was also placed horizontally and abutted against the cross-girder at L_6 directly opposite the double strut of the pivot panel.

As the temporary chord did not bear against the pins, L_6, next to the pivot panel, an unbalanced thrust was left for the batter posts, U_5-L_6, in the adjacent panel at each end, which must be transferred across the pivot panel. This was provided for by a timber strut (also adjustable) above the level of the pins, and bearing against the vertical posts, U_6-L_6, over the cross-girders.

As the chord stress is equal in both parts of a full panel and as the two temporary struts which were used to take the strain abutted against the pins at the main panel points and against opposite sides of the floor-beams at the same height at intermediate points, there was no strain in the floor-beams due to the temporary chord (or substitute), but merely a slight additional tension in the hangers.

In the full panel at each end of the bridge, L_0-L_1-L_2, tension was provided for by two adjustable rods passing over the intermediate pin, L_1, and connected by yokes with U-rods around the pins at the main panel points, L_0 and L_2. No provision was made for tension in any other part of the chord.

STRENGTHENING
WASHINGTON BRIDGE over HOUSATONIC RIVER
between MILFORD and STRATFORD, CONN.
CONNECTICUT COMPANY,
BRIDGEPORT LINES.

All the weight of the bridge when swinging, and (by the assumption made) nearly all of the dead load and a large part of the live load when the draw is closed, are delivered to the cross-girders at L_6 by the bearing of the bottom chord channels upon the cross-girders, whence it is carried to the center bearing, except for a small amount of unbalanced load carried by the turn-table wheels. It is evident that if the chord channels were removed entirely from the top of the cross-girders and no other provision was made for supporting the bridge, it would drop until a bearing of the vertical or batter posts was reached on the cross-girders. To prevent such a drop, four wedges $\frac{5}{8}$ in. thick were driven under each pin, L_6, just inside the webs of the channels forming the vertical post, and outside of those forming the main diagonal, U_5-L_6.

The longitudinal latticed struts between the cross-girders under the trusses were corroded very badly and had to be renewed; and readjustment was required in some of the truss members.

Details of Design.

In the first five sub-panels from each end of the span (see Plate XV), each compression member was composed of two pieces of 10 by 12-in. hard pine timber, separated by a forged steel wedge sliding vertically between cast-iron caps on the timbers, thus allowing for adjustment in the length of the member.

The lower end of this strut was trimmed so that it would bear solidly against the web and bottom flange of the intermediate floor-beam, while the upper end was cut down to a width of $8\frac{3}{4}$ in., and sawed off square to butt against the diaphragm of a steel cap with $\frac{3}{4}$-in. jaw-plates bolted one on each side of the timber. These jaws projected beyond the end of the timber and diaphragm, and had their ends cut out semi-circularly to fit against the main truss pin. Between these jaw-plates, and bearing against the end of the timber, a $\frac{1}{2}$-in. diaphragm plate was attached to the jaws by two angles, 8 (or 6) by 4 by $\frac{3}{4}$ in., the rivets being countersunk in the diaphragm so as to present a flat surface for bearing on the end of the timber.

The wedge was $3\frac{1}{2}$ ft. from the floor-beam end of the strut, and had two planed surfaces, each with a slope of 1 in 8, sliding between planed surfaces of the cast-iron caps on the timbers. Two $1\frac{1}{4}$-in. bolts, passing through the wedge and through a washer plate 12 in. square

by $\frac{3}{4}$ in. thick, were used to draw the wedge into place and to prevent it from slipping. Two scabs of 12-in. channels, 5 ft. long, were bolted to the strut, one on each side, to maintain the strut in proper line. These scabs were secured to the component timbers by nine $\frac{3}{4}$-in. bolts for each timber, three of which passed also through the cast-iron cap. The holes in the scab channels for the bolts for the lower, and shorter, timber were $\frac{13}{16}$ in. in diameter, while those for the bolts for the other timber were slotted to $2\frac{3}{4}$ in. in length. These bolts were left loose until the wedges were drawn up the full amount, and then tightened. The slopes of 1 in 8 (or $1\frac{1}{2}$ in. per ft.) were adopted for the wedge as nearly balancing the friction, if the faces of the wedge were well greased, the coefficient of friction being estimated at about 0.15.

Later experience confirmed this estimate, for when the bolts were slacked off, it required the tap of a hammer (in some cases a hard blow) to loosen the wedges.

In the half-panel next to the pivot panel (Plate XVI), the strut was made similar to those in the first five half-panels except that instead of the jaw connection for the pin at L_6, the strut was placed horizontally with a square end of the timber abutting against the web of the cross-girder under the pin, L_6. Blocking underneath and at both sides of the strut held it securely in place.

In the pivot panel a double strut was used. It was laid horizontally and level with those in the adjacent half-panels, but with one line of timbers on each side of the permanent latticed steel strut between the cross-girders, which (except one diagonal temporarily omitted) had been previously renewed. These timbers were bolted together through spacing blocks at three points, and had double cast-iron caps for wedges sliding horizontally, the two wedges being drawn in by two $1\frac{1}{4}$-in. rods passing through both wedges. At the expansion joints, 10-in. scab channels, similar to the 12-in. channels in the other panels, were used, but they were placed on top of and underneath the timbers. Blocking held the struts in place at points of bearing against the cross-girders and to distribute the pressure of the two struts of this panel so as to oppose the single struts of the adjacent half-panels without straining the webs of the cross-girders.

A strut was placed 13 in. (on centers) above the chord in the pivot panel to take the unbalanced thrust of the diagonal posts of the adjacent panels. Its construction was similar to that of the other

timber struts, and its ends butted against blocking on the channels of the vertical truss posts, blocking also being placed within the post to stiffen it locally.

In the full panel at each end of the span (Plate XV) the temporary $\frac{3}{4}$-in. rods were provided with turn-buckles for greater convenience, although adjustment was possible at the yokes where the main rods were connected with the U-bolts passing around the pins.

Specifications.

As is frequent in the writer's practice in the design and construction of such bridges or their repair, the specifications prepared by George F. Swain, Past-President, Am. Soc. C. E., and issued by the Massachusetts Railroad Commission, were adopted as the basic specifications for this work. As the proposed method of conducting the reconstruction required great care in its execution, or it would result in disaster instead of an improvement, supplementary specifications were prepared going into more than usual detail as to the methods to be used, precautions to be taken, and the order in which the work should be performed.

It was provided that the electric railway traffic should be suspended across the swing span during the progress of the repairs, and that other traffic should be restricted at all times to the half-width of roadway away from the truss on which work was being done at the time. In preparation for renewing the chord of the north truss, the sidewalk was to be removed and stored properly so that it might be replaced after the chord had been renewed.

The strengthening of one truss was required to be completed before work should begin on the other; and for each side of the bridge it was prescribed that the work should proceed in the following order:

The new longitudinal strut in the pivot panel under the truss between the cross-girders, should be placed and entirely riveted, except as noted, before any work is done on the truss itself.

Obstructions to placing the temporary chords, such as tie-plates and lattice bars, might be removed when necessary, but in such case temporary blocking and clamps should be placed in order properly to stiffen the chord channels.

All the temporary material for one truss was to be put in place and the slack taken up (but without strain), and examination was to be

made of each member to see if the anticipated additional wedging would leave the wedges within the prescribed limits of position, before the wedging should be begun, which was to relieve the main chords. The driving of these wedges was to begin at the pivot panel and proceed thence toward the ends, keeping the conditions approximately equal in the corresponding panels of the two arms. Wedges were to be well lubricated, and when fully drawn into the position which should remove all the strain from the main chords, they should bear for at least three-quarters of their length on the caps. All the bolts in the scab channels for the temporary struts were to be put in place and the nuts placed on the ends of the bolts, but left loose until the wedges were in their final positions. After the wedges were adjusted so that no strain whatever was left in the main chords the nuts must be tightened before any chord section could be removed.

It was specified that the entire temporary chord, including the adjustable rods of the end panels, should be in place and satisfactorily adjusted so that the main chord should be entirely free from strain, and the bolts through the scab channels tightened up, before any section of chord channel might be removed. The renewal of the chord channels should begin at the ends and proceed toward the pivot panel, only one section of chord channel being off at once, the lacing and tie-plates being bolted on as soon as practicable. Where the temporary work prevented immediate replacement of tie-plates and lacing, blocking and clamps should be used to stiffen the new chord channels similar to those specified for use with the old ones before renewal.

Wedges on the cross-girders under the pins, L_a, were specified to be driven before the old chord was removed, and to be withdrawn after the new chord sections should be in place; after which they were to be redriven to a firm bearing and secured in such a manner as to prevent their working out. At the time of writing the specifications it was not realized that the pin-holes in the chord channels had been so deformed by rust and overstrain that a settlement of from $\frac{1}{8}$ to $\frac{5}{16}$ in. had occurred at these points, requiring a corresponding lift of the whole bridge in order to allow the new chord channels to be put on.

The experience in driving the wedges the first time led to the cancellation of the requirement for their withdrawal and redriving. It was specified that short pieces of the inside channels at L_6 (there being

four channels in each chord section in the pivot panel) should be left in place to help deliver the weight of the bridge to the cross-girders.

Precautions Taken to Insure Safety.

From the inception of this method of renewing the truss chords, it was fully appreciated that any carelessness, either in design or execution of the work, would be fraught with danger; so special precautions were taken to insure its success. Consideration was given to the matter of economy, but when the question was the choice between low cost attended by danger and a somewhat higher cost coupled with safety for life and material, there was no hesitation in choosing safety. In its basic principles, the method proposed was so decidedly economical that there was less incentive to reduce the cost by the last cent possible, or to use too delicate scales in balancing safety against cost.

Extensive experience in the conduct of repair work brought a realization that, even more than in new work, carefully prepared specifications and plans were not by any means a guaranty that the actual work would be done as indicated by them. Therefore, when the plans were presented, it was stipulated that, if they were adopted, the work must be done under careful engineering supervision by a contractor, foreman, and crew who had been found dependable on other similar undertakings.

It was recommended, also, that payment for the work should be put on such a basis that undue desire for profit should not lead the contractor into careless methods. Arrangements were made to give the writer absolute jurisdiction, and that he should be represented at all times on the work by a trusted assistant as resident engineer; also, that he should be present in person during the more critical stages of the work. A contractor and foreman who had aided the writer and his staff many times in seeking "safety first" on other critical work, and had inspired complete confidence, were chosen to do the work, which was carried on under a "force account" contract.

In many cases the stresses to be provided for would have permitted the use of smaller timbers, and correspondingly smaller wedges, caps, etc., for the temporary work, especially if it could be assured that they would be subjected to no other strain than that of direct compression parallel with the axis of the timber. Practical consideration of all the demands that might be made upon them, however, prompted the use

of 10 by 12-in. timbers throughout, and wedge and channel reinforcement of a uniform type, as far as practicable.

As a further precaution, extra timbers, wedge, caps, and bolts were provided for use in an emergency, and timbers and blocking were made available so that, in case of difficulty in drawing up the wedges, the bridge could be swung open and blocked up on the fender pier. Except two wedge bolts, these extra supplies were not required, and after the completion of the work the timbers were returned to the lumber company without other expense than the mere hauling to and from the bridge.

Although it was considered safe to swing the draw at any time during the progress of the work, it was thought desirable as an additional precaution to avoid such turning if practicable. Preparation was made, therefore, to execute the work during the season in which navigation would be closed by ice. It is evident that the writer can lay no claim to being righteous, for "the good book" states that the "fervent prayer of a righteous man availeth much." Certainly his prayer for a long closed season was fervent; but the winter of 1912-13 proved to be a very unusual one, and the longed-for ice came in such moderation that navigation continued without interruption. Nevertheless, the work went ahead and was completed with no mishap whatever.

Construction Work.

All materials for the work, both for temporary use and for permanent construction, were made ready and collected on or near the bridge before work was commenced on the existing structure. A barricade was erected at the end of each approach span, just outside of the permanent gate, and a fence was built for the whole length of the swing span to confine the traffic to the south side of the draw, leaving a little more than half the width of the roadway clear, and protecting the men at work on the north truss. The sidewalk floor outside the north truss was taken up, and the north tender's house (used only for storage of supplies) was removed except the roof, which was hung by slings from above because of the counter rods of the truss passing through it.

The first work, except that of preparation, was the removal of the longitudinal struts between the cross-girders of the turn-table and their replacement with new material. This was completed and riveted (except one diagonal omitted for the time being to allow the wedge

cap of the temporary chord to pass through the strut) before any work was done on the truss chord itself.

The temporary chord (or temporary substitute for the chord) was then put in place, but without strain, for the whole length of the north truss. Each sub-panel strut was handled in two lengths, the long timber with its wedge-cap and the jaws for the pin comprising one part, and the short timber and its wedge-cap with the channel scabs bolted on loosely forming the other. These two lengths were put together in place, the bolts put through the scab channels and the long timber, and the nuts caught on the bolts, but not turned up (see Fig. 6).

This held the strut (minus the wedge) sufficiently in position to release the men and the tackle for the heavier work of hoisting the wedge into place, after which the bolts and washer plates were added and the wedge was drawn up just enough to take up the slack. The lengths were made such that this condition left the wedge bearing for about half of its length on about half of the depth of the strut, as shown by Fig. 7.

In the pivot panel, the double strut was placed in a similar way, with one line of timbers inside and one outside (see Fig. 8) of the permanent strut between the cross-girders, except that the wedge-caps (being double caps serving both struts and passing through the permanent strut where the diagonal was omitted temporarily) were placed separately from the timbers. Consequently, the scab channels were also handled separately. This was done the more readily here because these timbers could be hung upon the permament strut. In this panel the channel scabs were on the top and bottom of the timbers, and the wedges were drawn horizontally from the inside and outside, a single pair of rods serving for both wedges.

Before placing the upper temporary strut of the pivot panel, the §-in. wedges, W_2, were driven under the main truss pins between the pins, L_6 and the cross-girders (or bearing girders). As these pin-holes had been enlarged by rust and overstrain, there had been such a settlement as to require a lift ranging from $\frac{1}{8}$ to $\frac{5}{16}$ in. The cramped space for these wedges added to the difficulty of driving them into place, but this was accomplished satisfactorily. Afterward, the upper temporary strut was placed between the truss verticals. The wedges under these pins were left in place, not being withdrawn temporarily as specified. It

was not found necessary to pin them to prevent their working out. Blocking was used inside the posts, and between the strut timbers and the posts, to distribute the strain and stiffen up the post channels. In this temporary strut the scab channels were placed on the upper and lower sides of the strut, and the wedge was driven horizontally.

Temporary tension rods, TR_1, in the end panels (see Plate XV) were placed by first inserting the long rods through the lacing of the chord and passing their ends through the pin-caps of the temporary struts. Yokes were then put on the ends of the rods and the nuts turned up, the loop ends put around the pins and through the yokes, and the turnbuckles added and turned up sufficiently to take up the slack.

In placing the temporary struts or rods, it frequently became necessary to cut away the tie-plates and lacing bars, but whenever this was done suitable blocking and clamps were put on to stiffen the chord channels properly (see Fig. 9). This was done also to stiffen the channels of the new chords before the temporary struts were removed, so that the tie-plates and lacing could be bolted on. At some pins, a slight readjustment of the pin-packing was required to allow the proper insertion of the jaws of the temporary struts.

When the temporary work for the renewal of the chord of the north truss was in place for the whole length of the swing span, with the slack taken up, but without taking any strain, all parts were examined carefully to see if any refitting was required. Everything being found satisfactory, the work of drawing in the wedges was begun, starting at the pivot panel and working toward the ends, keeping the advance approximately even in the two arms. At each wedge the nuts were turned up a little on the rods alternately, using a long-handled wrench with the handle lengthened by the addition of a piece of pipe so that three men could work together on the wrench while a fourth assisted by striking the head of the wedge frequent blows with a sledge. The chord was considerably relieved of strain in the pivot panel, L_6-L_6' (see Fig. 5), and the adjacent panels, L_4-L_5-L_6, toward each end before any wedging was done in more distant panels. The middle panels, L_2-L_3-L_4, of each arm were then wedged until there was hardly any strain left in the truss chord. The men returned to the pivot panel and those next to it on each end, and the strain was entirely taken out of the chord. After this, the remaining strain in the middle panels was removed, and the end panels, L_0-L_1-L_2, were relieved of all possibility of strain,

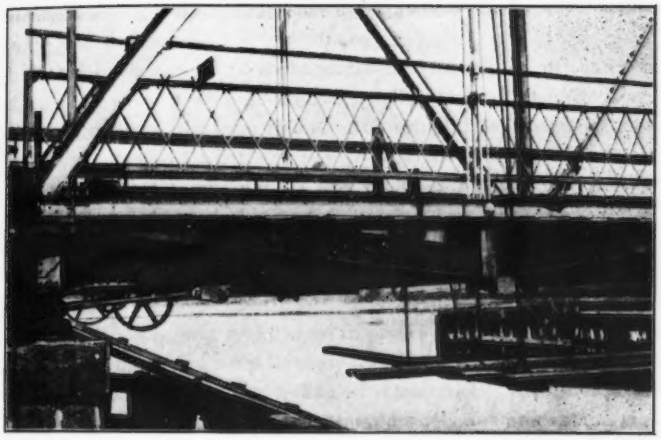

FIG. 6.—TEMPORARY CHORD IN PLACE AT WEST END OF SOUTH TRUSS.

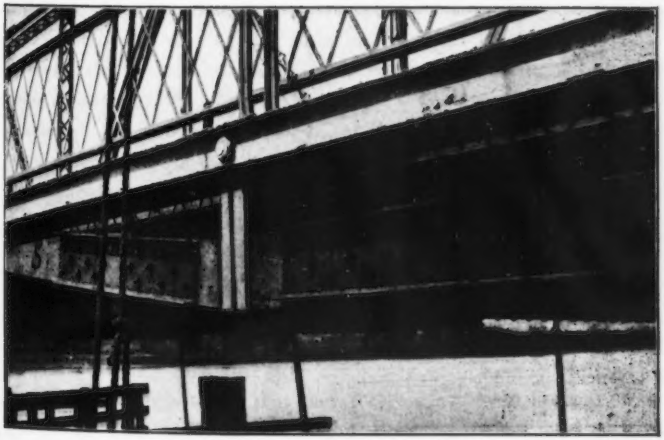

FIG. 7.—TEMPORARY BOTTOM CHORD, L_4-L_5-L_6, IN SOUTH TRUSS.

whether the ends of the span were lifted or were swinging free, by wedging the compression struts and by tightening up the turn-buckles on the tension rods.

As had been expected, a slight strain was now found in the chord of the pivot panel and those adjacent to it, although they had been previously entirely free from strain. Accordingly, the wedges in these panels were drawn in a little more to relieve the chord again entirely. Then each section of channel for the whole of the span was sounded carefully to make sure that it was absolutely "dead", and every nut on the wedge rods and each tension rod in the end panels was tested in order to be sure that the rods of each couple were dividing the stress about equally.

When everything was found to be in proper condition, the nuts were turned up tight on the bolts through the channel scabs, and the work was left for the night with a feeling of satisfaction. All pin-nuts for this truss were loosened so as to be removed easily and quickly (in most cases by hand) when required, but left on the pins, and so close to the chord channels that no channel could slip off the shoulder of the pin before its removal was desired. Several pin-nuts were broken in their removal, but a supply had been provided for this contingency. As more new nuts were required for the north truss than had been anticipated, an additional reserve was obtained in order that there should be no lack later.

The first work the next morning was to retest carefully all details to see if any change had taken place during the night. Everything being satisfactory, the lacing and tie-plates were removed from the outer channel of the first panel, L_0-L_1-L_2, at the east end, and this channel taken off. The test of the plan of renewal was not to be delayed greatly; for hardly had this channel been removed when a whistle was heard calling for the opening of the draw. There was no time for substituting a new channel, so the work was stopped, all staging connecting the moving with the fixed structure was shifted to be carried entirely by the one or the other, and orders were given to open the draw.

During the whole time the bridge was open, the engineers and the foreman carefully observed the temporary structure, sounding the steel chord channels to see that they received no strain because of the movement. The result of this observation was so reassuring that thereafter no hesitation whatever was felt about opening the bridge as often

as desired; in fact, after the draw had been swung a few times, the work went on while the bridge was open just about the same as when it was closed, except for the removal of planks and ropes connecting it with the piers and fixed spans. Several times some of the workmen did not even notice that the bridge had moved until they heard the noise of the machinery lifting the ends after the bridge was closed.

When the draw was closed again, the new outer chord channel was put in place, and the hanger for the end floor-beam bolted to it. Then the inner channel was removed and a new one substituted. When both new channels of this section of the chord were in position and the nuts replaced on the truss pins, as many of the tie-plates and lacing bars as practicable were bolted on, and such blocking and clamps added as were necessary properly to stiffen that portion of the length which was left disconnected. Bolts were put in the gussets connecting the chord with the end floor-beam; the latter bolts were replaced by rivets as soon as practicable, but those in the tie-plates and lacing were allowed to await a more convenient time.

The renewal of the second and third panels followed rapidly, completing the east arm of this truss except for a short space near the pin, L_6. In like manner, the lower chord of the west arm of this north truss was renewed for an equal length; after which the new outside channels of the pivot panel were placed and the inside channels of this panel were cut off a few inches from the pin. As required by the specifications, a short piece of each of these inside channels was left in place to assist in delivering the load of the truss from the pin to the cross-girder.

As fast as sections of chord were added, the splice-plates were bolted tight with bolts in about half of the holes and drift-pins in the other half. Riveting of the splices was done as soon as convenient after the temporary work was removed, but riveting of the tie-plates and lacing, as well as the replacing of the sidewalk, was allowed to await the convenience of the work.

When the whole chord was in place and the splices bolted, all anxiety about the success of the plan was over, but some difficulty was experienced in the removal of the wedges. As their slopes were slightly less than the angle of friction of the bearing surfaces after the lubricant had been squeezed and dried out, some coaxing was required in starting them. In fact, in some cases it proved harder to force them out than it had been to draw them into place. It was considered unsafe

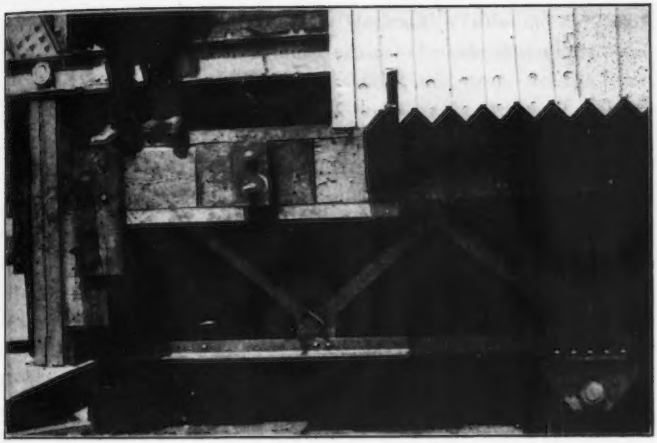

FIG. 8.—TEMPORARY BOTTOM CHORD IN PIVOT PANEL OF SOUTH TRUSS.

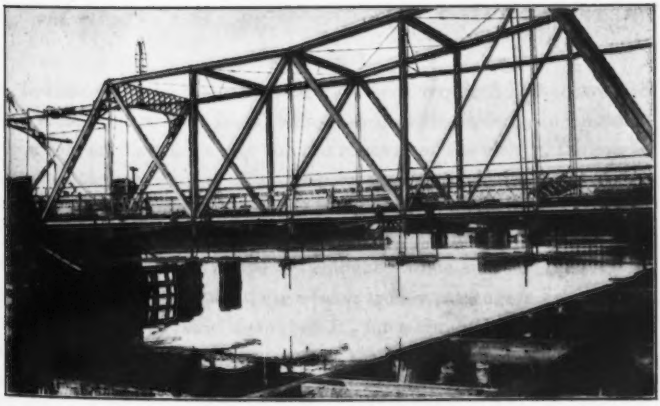

FIG. 9.—WEST HALF OF SOUTH TRUSS WITH TEMPORARY CHORD IN PLACE.

to remove both bolts entirely from a wedge, because a sudden movement of the wedge might endanger the chords by the impact as well as cause the loss of the wedge. The bolts were slackened a little and the wedge "teased" along by blows of a hammer against the side of the broad end, where it extended beyond the under side of the strut. In the worst cases, one of the bolts was slackened off and the other removed entirely, allowing a bar to be put through the hole in the washer plate and the wedge to be driven out by blows against the thin end of the wedge.

Work on the south truss was similar to that on the north truss with two important exceptions, namely, all the men were experienced in their respective duties, and the inconvenience of the sidewalk brackets, etc., was absent; progress therefore was more rapid. In one respect, however, work on the south truss was more difficult, because there was greater distortion and corrosion of the pin-holes at L_6 over the cross-girders. This caused the most troublesome operation on the whole work, as it added to the difficulty of raising the truss to its original position. The identical material was used for temporary work for the south truss that had been used for the north, except that two new bolts were required for drawing in the wedges, to replace those with worn threads.

After the new chords were in position, riveting and some adjustments of floor-beam hangers completed the restoration of the bridge to a capacity considerably greater than before corrosion and distortion had injured it.

Conclusion.

In comparison with what would have been required had the repairs been made by providing for a detour, so that the draw span might be blocked up on the fender pier for the renewal of the chords, the money cost and the interference with traffic by this method of reconstruction were remarkably small.

The total cost of the work, exclusive of engineering expense and that of watchmen, was $5 900. Vehicular traffic was confined to the half-width of bridge for about six weeks; trolley passengers were obliged to transfer, with a walk of about 300 ft., for a similar period. Shipping suffered no obstruction whatever, for the bridge was swung as freely as usual.

Although no definite estimate was made of the cost of a detour, with a temporary viaduct and jack-knife draw, it is believed that this

cost, with provision for car service, would have been at least $100 000. This plan would have saved the transfer of trolley passengers, but all traffic would have had an increased length of haul of 300 ft. (about equal to the distance that traffic was restricted by the adopted plan), and an undesirable grade at each end of the detour would have been introduced. As a temporary draw is slow of action, the interruption to traffic probably would have been as great as it was with the short gauntlet required by the plan described in this paper.

Interference with navigation surely would have been greater with a temporary trestle and jack-knife draw, unless there was justification for the suspicion several times expressed when a tug passed up the river a short distance, and returned soon without any apparent reason for the trip. It was intimated that these trips might have been taken in the hope of a refusal to open the draw, in order to obtain a basis for a damage claim. No cause for such claim was given, however. The time required for the work would have been much greater with such a detour than was the case by the method adopted.

The cost of a detour might have been reduced somewhat by omitting provision for the use of cars on the temporary bridge, but even with this saving, it would have involved many times the cost of the method adopted. Such an omission would have required a transfer of trolley passengers and necessitated their walking about ¼ mile.

Although the success of the method was never doubted by the writer, he realized that some individual might be criminally careless and neglect his plain duty, or that the seriousness of some otherwise minor accident might have been increased because of the reconstruction work. There was therefore a feeling of relief when the work was safely completed, also intensified by the fact that an eminent engineer had expressed a fear that "the bridge would be dropped into the river before the task was finished."

Hearty appreciation is felt for the constant interest shown by James L. Parker, Assoc. M. Am. Soc. C. E., the writer's Principal Assistant, and Guy Pinner, Assoc. M. Am. Soc. C. E., his Detail Designer and Resident Engineer during construction, for their careful study of the problems involved; also to the United Construction Company, the contractor, and to Mr. Charles Sones, their faithful and careful foreman, and to each of his men for their helpful attitude, so necessary for the successful prosecution of the work without the slightest accident.

DISCUSSION

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—The author is to be congratulated on the wonderful ingenuity shown, the marvelous economy of construction, and the successful manner in which this work was carried out. Only those familiar with this kind of work can realize how many opportunities there are for careless assistants to drop the bridge in the river, as in the case of the Bussey Bridge, many years ago, and others.

The speaker would like to ask Mr. Keith whether or not he considered reinforcing the bottom chord with concrete instead of removing it? It hardly seems possible that any cheaper method could have been found than the one adopted.

Mr. Pinner.

GUY PINNER,* ASSOC. M. AM. SOC. C. E.—Little can be added to this excellent paper, except that Mr. Thomson's question as to whether strengthening was considered might be answered.

When the problem first came to the speaker's attention in Mr. Keith's office, it was thought that the old chords could be strengthened by adding section in some manner, but, after a thorough investigation, it was found that there was not enough section left in the old channels on which to begin work, so the thought of strengthening was abandoned in favor of entire renewal.

The author lays considerable stress on the matter of "safety first", which was always kept in mind in starting all details of the construction, as well as in making the plans for the work. When this work was started, it was thought advisable to test the "safety first" ideas of the foreman whom the author has mentioned, and, therefore, when the scaffold hangers, which were made by a local blacksmith, were received on the work, several of them were tested and found to be satisfactory and about as the calculations indicated.

When the erection of the new lower struts between the cross-girders was begun, the foreman projected several 3 by 8-in. or 3 by 10-in. timbers from the upper longitudinal truss struts in the center panel for swinging them into place. They did not appear to be strong enough to carry the weight of the struts, but calculations showed that the timbers would have an extreme fiber stress of about 1 400 lb. per sq. in. After these tests, the conclusion was reached that the foreman could be relied on with regard to safety, which conclusion was proved later, as the work was completed without an accident.

The gang was a very good one for this class of work, each man being a hard worker, thoroughly dependable, and following all directions to the letter. Although the work was explained to the men several times, they never seemed to grasp the intent and importance of it,

* New York City.

Mr. Pinner. until probably the last week, after all the temporary chords had been removed. They had discussed it frequently among themselves, but could not understand why it was necessary to do so much tightening and adjusting on the bolts which passed through the adjustable wedges. When the work was finished, however, they stated that they would like to be sent on the next contract of this nature, for they felt that they could make a better job of it.

Mr. Hardesty. SHORTRIDGE HARDESTY,* ASSOC. M. AM. SOC. C. E.—It is instructive to note that Mr. Keith's plan of reconstruction gave direct central stresses in all the temporary struts; also that, with one exception, these struts bore centrally on the truss pins or abutted squarely opposite each other, thus avoiding bending or twisting stresses in other truss members. It was found advisable to put the strut, *TC6*, 1 ft. 1 in. above the pins at L_6, thus throwing bending into the post, $U_6 L_6$. This bending was small, however, being merely that due to the horizontal component of $U_5 L_6$. The author's solution, therefore, was not only a very practical one, but was theoretically correct as well. The method of bringing the new chord into action also insured that the stresses would be properly distributed.

It would seem that the eminent engineer who expressed the fear that "the bridge would be dropped into the river before the task was finished" had not examined the author's details and specifications very thoroughly. The bridge was probably as safe with the temporary wooden chord as with the old steel chord, which must have been near failure at some of the pin-holes.

Mr. French. JAMES B. FRENCH,† M. AM. SOC. C. E.—Work such as that described by Mr. Keith is not monumental. It leaves little behind to attract favorable attention, but, at the same time, it often calls for greater skill on the part of the engineer and draws on his resourcefulness and ingenuity to a greater extent than the execution of more monumental works which remain to be looked at and admired. This structure was, presumably, not any more beautiful after these repairs were made than it was before, and it is doubtful whether any of the people who were carried over it while the work was in progress had any appreciation of the care that was being taken to protect their lives.

It is obvious that the work described could only have been done as the result of careful investigation, careful planning, and careful supervision at every stage. Any mistake, either in the planning, execution, or supervision of the work, could easily have resulted in dropping the bridge into the river, as the author's friend prophesied would happen, and serious loss of life might have resulted.

Although the author's precaution to have all the material on hand and an extra supply of tools available before the work was started

* Kansas City, Mo.
† New York City.

might not seem worthy of note, the importance of such precautions in cases where human lives are concerned cannot be exaggerated. The speaker has had many occasions to be thankful for the training received years ago under a very capable practical bridge erector in rebuilding railroad bridges under traffic. Great pressure was sometimes brought to bear on this man to make a spectacular start before he was thoroughly ready, but under no circumstances would he in any way weaken the old structure until he had positive first-hand knowledge that all the materials and tools required for the completion of the new one were just where he could put his hand on them. Such schooling is not without value to any one responsible for operations of the kind described in this paper. Mr. French.

The character of the contract entered into for the execution of this work also seems worthy of comment. It is, of course, an axiom in the writing of specifications that it is permissible either to specify the result to be obtained, allowing the contractor full discretion in the choice of the methods to be used and holding him fully responsible for the result; or to specify in detail the method and procedure to be followed at every stage, with the understanding that the contractor is thereby relieved of responsibility for the result. Making a contract of the first sort in a case like the one described by Mr. Keith has more than once led to disastrous results, and considerations of public safety make such practice particularly dangerous unless bidding can be confined strictly to contractors known to be thoroughly competent and to have conscientious regard for the public safety. Conspicuous examples illustrating the disastrous consequences of putting public work of this character under contracts which practically invite the contractor to take chances, will probably come to the minds of many readers of this paper, and such disregard for the safety of the traveling public should be condemned.

It has been the speaker's experience that railroad companies, which certainly receive their share of public criticism, are generally much more careful to take adequate precautions to protect human life in the execution of work of this kind, than municipalities. This experience has been gained largely in grade separation work for the Long Island Railroad Company, in Brooklyn, N. Y., and it is a pleasure to testify that in all important situations involving the protection of human life, this company has gone to the expense of having plans and specifications prepared, not only to cover the permanent construction, but the temporary structures and falsework, also carefully worked out programmes of procedure to protect the traveling public at every stage of the work.

In order, however, not to hamper the ingenuity or resourcefulness of the contractor, or to relieve him of responsibility, these plans and specifications relating to falsework and procedure have not been in-

Mr. French.

sisted on as final, but the contractor has been given the alternative either of following them or submitting others, equally definite, for approval. In no case, however, was the particular work allowed to proceed until the contractor and the engineers of the railroad company had come to a definite understanding as to how it was to be handled in detail. In this way, contractors and engineers have shared the responsibility, and the public has received the most effective protection practicable.

The author has apparently been employed by a corporation having the same high regard for its obligation to the traveling public and, in the speaker's opinion, both he and the corporation are to be congratulated on the very skilful and economical execution of a particularly difficult piece of work.

Paper No. 1449

PHYSIOGRAPHY OF WATER-SHEDS AND CHANNELS, AND ANALYSIS OF STREAM ACTION OF SOUTHERN CALIFORNIA RIVERS, WITH REFERENCE TO THE PROBLEMS OF FLOOD CONTROL *

By A. L. Sonderegger, M. Am. Soc. C. E.

With Discussion by Messrs. Charles A. Pohl, Francis H. Wright, H. F. Dunham, Fred D. Bowlus, and A. L. Sonderegger.

Synopsis

Although the basic forces which have brought about destruction by flood flow, and, in consequence, the necessity for flood control in Southern California, are the same as in the Eastern and Northern States, they operate in this country under widely different conditions with the result that their effect is intensified.

The chief physiographic features of Southern California are the result of block-faulting, the mountains being raised blocks and the valleys sunken blocks. During the process of deformation, materials were eroded from the mountain ranges and transported by water into the depressions or sunken valleys, producing a valley fill made up of gravels, sands, and clay. Apparently, no glacial action has occurred in Southern California.

The sunken valleys present basins of enormous dimensions, embracing areas up to 100 sq. miles, and depths of more than 1 000 ft., and

* This paper was presented before the Southern California Association of Members of the American Society of Civil Engineers, at its meeting of March 12th, 1919, and also before the meeting of the Society on October 1st, 1919.

they are the logical storage reservoirs for the flood waters. The velocity of percolation of ground-water is exceedingly low, ranging from ½ mile to 4 miles per annum, the water remaining fresh and potable for indefinite periods. There are some surface storage reservoir sites in the San Jacinto block and in the San Bernardino block, but there is none of any consequence in the San Gabriel Range.

In Southern California, 75% of the precipitation occurs in the months of December to March, inclusive, and limits flood discharge to those months. In summer the river channels are essentially dry. Flood flow, therefore, may begin to act on a dry river bed, which, subsequently, becomes saturated and is finally exposed to a protracted receding stream flow until it dries up.

The short courses of the rivers from their source, and more particularly from the mouth of their canyons, to the sea, traversing an alluvial formation on steep grades, produce below the mouth of the canyons a rapid succession of alluvial and erosional stream activities superimposed upon the general phenomenon of valley construction. The effect is an alternation of stretches where the stream inundates the adjoining country, with sections where it is in a deep cut and undermines the banks.

The most important law affecting stream flow in a natural channel crossing alluvial deposits which readily succumb to erosion, is expressed as follows: The stream has a tendency to charge itself with a burden which is in exact proportion to the power of the water to carry. With constant discharge this power or capacity to carry a burden varies on an average with the fourth power of the mean velocity (Gilbert), or with the fifth power of the bed velocity (Deacon).

The profile of a stream shows a gradually flattening gradient from the source to the sea. (See Fig. 1.)

Every one of the larger streams shows the following characteristic sections: First, a mountain section extending from the source of the stream to the mouth of its canyon. It has the steepest grades and highest velocities, and is the original source of all débris. There are no agricultural or other improvements of any consequence in the mountains, and there is no damage from flood flow.

Second, a débris cone, defined as extending from the mouth of the canyon as far down stream as action is alluvial. (See Fig. 2.) Erosional activity and the transportation of detrital matter

in the mountains being the cause, the formation of the débris cone is the effect. The cone is a fan-shaped area on which the river deposits the larger portion of its débris in traction, and only a little of that in suspension. The stream course is along lines of steepest gradient, issuing from the mouth of the canyon. The danger lies in a shifting at the mouth of the canyon, causing the stream to pursue an entirely new course. The cone offers the most favorable opportunity for the absorption of flood water. The muddy water, during peaks, prevents seepage, and present methods of artificial spreading have not succeeded in reducing the peak flow.

For the San Gabriel River cone it has been proposed to deepen the existing channel and construct embankments of the excavated materials, leaving wide berms. This channel is to be maintained by dredging whenever necessary.

Third, a valley section extending from the foot of the débris cone to the head of the delta, with a channel alternately under erosional and alluvial stream action. The effect of erosion on a channel during the peak flow is a scouring of the bottom, and during a receding flood an undermining of banks, causing the liberation of large quantities of débris and their movement down stream. (See Fig. 3.) The damage is caused by the undermining of the banks. Under alluvial action the stream runs in a shallow channel, depositing a portion of its sediments both in traction and in suspension, and inundating the adjoining country. (See Figs. 4, 5, and 6.) Present methods of improvement are bank protection in erosional channels, and levee construction in alluvial ones, no attempt being made to check erosion of the channel floor.

Fourth, a delta extending from the last erosional channel of the valley section to tide-water. (See Fig. 7.) This is a typical deposit cone, the stream shifting more frequently than on a débris cone. Damage is caused by inundation. Coming to the sea beach there is a pronounced littoral current which tends to deflect estuaries southeastward. (See Fig. 8.) In the larger streams the tidal sloughs and lagoons at their mouths furnish tidal prisms of sufficient magnitude to keep their estuaries open the year round. With the smaller streams ocean breaker action closes the estuaries between flood seasons. The methods of protection contemplated for the Rio Hondo-Los Angeles River are: Levee construction along the course of deepest gradient, and rock jetties to stabilize the estuary.

The magnitude of the flood flow is the basic trouble; but in the absence of suitable storage sites it may be impossible, in many instances, to reduce either the peak or the average flood flow. The local problem resolves itself into one of preventing both erosion and movement of detrital matter.

Theoretically speaking, effective control of floods implies the following ten requirements:

1. That the stream arrive at the mouth of the canyon free from débris in traction.
2. That the stream arrive at the mouth of the canyon delivered of a large percentage of its sediments in suspension.
3. That it be prevented from resuming erosional action on its way down the cone.
4. That means be provided to induce the absorption on the débris cone of the largest possible portion of the flood flow, particularly of the peak load.
5. That erosional stream action be eliminated in the valley section by fixing the channel floor and protecting the banks.
6. That inundation areas in the valley section be defined and controlled.
7. That the stream arrive at the delta delivered of the major portion of its débris, both in traction and in suspension.
8. That inundation areas in the delta be defined and controlled.
9. That the estuary be made secure against closure through ocean wave or current action.
10. In each case exceptional as well as small flood discharge must be taken into consideration, and particularly the cumulative effect of exclusively moderate or small flood flow over a series of years.

General Conditions.

The characteristic physical features of Southern California are a coast line running roughly in a southeast direction and a series of mountain ranges running parallel to the coast line, separated by valleys made up of alluvial fill from these mountains.

The great variation in climatic conditions produced by these mountain ranges, roughly speaking, divides Southern California into three zones, in which the problems of flood control take on different

aspects. The first zone comprises Ventura, Los Angeles, San Bernardino, Riverside, and Orange Counties (with the exception of their desert areas). The ranges attain elevations up to 10 800 ft., and there is a characteristic seasonal rainfall in the valleys, roughly estimated at 16 in. The second zone embraces San Diego County, exclusive of its desert area, with mountain ranges rising to 6 500 ft., and a typical valley rainfall of about 14 in. The third zone includes the desert territory of the Mohave, Coachella, and Imperial Valleys.

Since the question of flood control is more acute in the northern part of Southern California, this paper will be confined chiefly to the first of these zones, and only touch the others; however, it should not be understood that there are no flood-control problems in San Diego County, nor in parts of the desert.

Geology.

The chief physical features of Southern California are the result of block-faulting. (See Plate XVII.) Generally speaking, the crustal movements which ultimately produced the present aspect of the country, raised the mountains, and simultaneously therewith the valleys between the mountain ranges sank. While this process was going on, materials were eroded from the mountain ranges and transported into these depressions, producing the valley fill as it appears to-day, so that the valleys and the coastal plain are not valleys of erosion but of construction. At the end of the Mesozoic period this part of the Pacific Coast was characterized by mountain ranges consisting of metamorphosed sediments, such as schists and gneisses, with intrusions of granite. During the Tertiary period, destructive erosion reduced these ranges to a very material extent, producing on land unstratified deposits of alluvial materials, such as boulders, gravel, sand, and clay, and in the ocean roughly stratified beds of conglomerates and more thinly stratified beds of fine sediments and clay materials, which later gave rise to the formation of sandstones and shales.

At the end of the Tertiary period the country was one of comparatively low relief. The elevation of the coast, as compared with its present elevation, was at least 1 800 ft. lower, and the sea beat against the San Gabriel Mountains or Sierra Madre Range.

At the end of the Tertiary period and the beginning of the Quaternary period, the coast was raised to not less than 700 ft. higher

than it is at present, followed by gradual subsidence to its present elevation.

The mountain ranges rise to nearly 11 000 ft., while the valleys, in general, slope from an elevation of 1 000 ft., more or less, down to tide-water. The valleys present a series of sunken basins or reservoirs which, in some instances, are practically completely surrounded by impervious formation, while in others they are open toward tide-water. Many of these basins are of a depth of 1 000 ft. or more, and cover large areas. The San Bernardino River basin, for example, has an area of more than 100 sq. miles and a depth exceeding 1 000 ft., bed-rock being at unknown depth. The basins, therefore, have enormous water storage capacities and become the natural recipients in their porous formation of large volumes of the rainfall running off the steep mountain slopes. Nature has thus provided storage for the flood waters of a magnitude compared with which the contents of the few artificial reservoir sites sink into utter insignificance.

In the northern counties of Southern California the porous beds of these valleys reach depths of 1 000 ft. or more, in fact, in many of them bed-rock has not yet been reached. This applies to the San Gabriel, the San Bernardino, the Pomona and the San Fernando Valleys. In San Diego County a different condition prevails. There, the valley fills are much shallower, reaching from 60 to 100 ft., and hence their storage capacity is quite limited.

As previously stated, block-faulting has been the chief agency in forming the present physiographic features. The most noted fault line is that of the San Andreas, which runs from Coachella Valley to San Bernardino Valley, and along the southern escarpment of the San Bernardino block northwest, along the northern margin of the San Gabriel block, toward the Tehachapi. (See Plate XVII.)

The San Bernardino block is tilted to the north, toward the desert, its steepest escarpment being to the south, just north of the City of San Bernardino. The top of this block is comparatively level, with numerous valleys and flats, and quite a number of good reservoir sites. Geologists tell us that these valleys are the remnant of the old topography, as it existed during the Tertiary period before the uplift.

The San Jacinto block is tilted to the west. Its steep escarpment is to the east, toward Coachella Desert, while to the west the slope is less abrupt. The eastern escarpment has a drop of as much as 10 300

ft. in a distance of 8 miles, while to the west it slopes from San Jacinto peak (Elevation 10 800) to the City of San Jacinto, about 9 000 ft. in 13 miles. This block also shows remnants of the old topography and has some reservoir sites. It is said that Perris Valley to the west of it, with its cupola-shaped granite buttes, is typical of the Tertiary topography which has undergone but little change.

The San Gabriel Mountains are assumed to be older than the San Bernardino Mountains, and to have been longer subjected to erosion, with the result that the flats have practically disappeared, and there are no reservoir sites of any consequence.

The main ranges consist of eruptive rocks, such as granite and diorites, and metamorphosed rocks, such as schists and gneisses, while the outlying lower ranges are mostly sedimentary. The latter is also the case with the Santa Monica and Ventura Mountains.

Generally speaking, the rocks are much shattered, and only the older granites, as we find them in Perris Valley, and in the Jurupa Mountains, near Riverside, are suitable for quarrying.

The fact that the mountain ranges run in series, and parallel to the coast, and the manner in which the outlying ranges were uplifted, has brought about a phenomenon peculiar to Southern California, in that the rivers have cut numerous gaps in the outlying mountain ranges, producing "narrows" which are characteristic of all the larger streams, and are seen in the narrows of the Los Angeles River at Elysian Park; of the San Gabriel River at Whittier; of the Santa Ana River at Colton; and of the Los Angeles and San Gabriel Rivers combined at Dominguez.

Physiography.

There are two factors that put Los Angeles flood-control problems into a class of their own.

The first is of meteorological origin, in that 75% of the seasonal rainfall occurs during the months of December to March, inclusive, resulting in a wet and dry season. Floods occur only during the winter months, while in summer the stream beds are practically dry.

Most of the smaller rivers are dry below the upper portion of their débris cones, except during storms. Even with the largest rivers, the ordinary flow is insignificant as compared with the flood flow or peak load. The action of the stream is, therefore, at the beginning of the

first storm, on a practically dry channel, and this action is widely different from that which occurs after the bed becomes saturated. Again, as a result of the semi-tropical rains on the steep mountain slopes, storm run-off is extremely "flashy", and it may happen that a flood channel that has been dry for six months may be filled to overflow within a few days. Finally, there is the process of the slow drying up of the stream. A receding flow is almost invariably alluvial in its action on the bottom of its channel, but may be under-cutting its banks, or causing saturated banks to cave, so that the condition of the channel at the end of the rainy season is often quite different from that during the flood.

The second factor is the short distance from the mountain peaks to the ocean. The air line from San Antonio peak, the source of the East Fork of the San Gabriel River, with an elevation of 10 080 ft., to the ocean is 44 miles, and the air line from the extreme water-shed of the Santa Ana River, with a maximum elevation of 10 630 ft., to the ocean is 84 miles. The length of the San Gabriel channel from the foot of the San Gabriel Mountains to the ocean, is only about 35 miles, with a drop of 750 ft., or an average of 21 ft. per mile. The stream profiles show the well-known parabolic curve gradually flattening out down stream. (See Fig. 1.) The short run, particularly from the foot of the mountains to the ocean, has produced in the stream channels a succession of sections in which erosional and alluvial action alternate.

Since it is in the very nature of things that the remedies to be applied to a section where stream action is erosional, must be widely different from those where it is alluvial, it becomes fundamental that the natural flood channel be studied, particularly in regard to the nature of stream action.

An erosional stream flows in a more or less rectangular channel of favorable hydraulic properties, sometimes with well-developed berms. It has a tendency to lengthen its course by attacking its banks and producing meanders, thereby flattening its grade and tending to establish equilibrium between its erosional power and the resistance to erosion of the stream bed.

During a flood two distinct erosional actions take place. First, there is scour of the bottom proportionate to the volume of flood flow, and the materials thus set in motion are transported down stream. As

the flood recedes, the bottom gradually rises again, and unless discharge drops off very suddenly, the bottom will be restored to the shape and elevation it had before the flood.*

The second phenomenon is the undermining of the banks, particularly along the outer banks of curves, and this results in a meandering course. At time of full channel the banks become saturated. With recession of the flood the external water pressure is withdrawn, and the banks cave, not only along bends, but also along straight sections. The falling earth is washed away and the damage done along banks increases with a protracted receding flood.

Fundamental Laws Governing Stream Flow.

The most important factor in stream flow is the relation of sediment to cross-section and slope. A stream running through an alluvial valley has a tendency to charge itself with a burden of sediment, which seeks to remain in exact proportion to the power of the water to carry it. It is, therefore, not enough to clarify a stream, but steps must be taken to prevent it from acquiring a new burden.

The scouring capacity of a river is supposed to vary with the square root of the velocity; but it is also very largely dependent on the depth of the flow. This is due to the increased weight. Shallow streams, as a rule, do not produce whirlpools and boils, while depth favors their formation.

Gilbert states that when the discharge is constant so that velocity changes with slope, then the capacity to carry a burden varies on an average with the fourth power of velocity, using the mean velocity instead of the bed velocity (near the bottom and which cannot be accurately measured).

Considering Gilbert's law, it becomes evident at once that even a small change in velocity must immediately affect the volume of burden carried to a considerable degree, and produce either scouring or a deposit.

The velocity itself is primarily dependent on the slope of the valley, and also on the shape of the channel. It varies in proportion to the square root of both the slope and the hydraulic radius. Width is a factor, a broad channel carrying more débris than a narrow one, but velocities and carrying capacity also increase with increasing depth.

* *Professional Paper No. 86, U. S. Geological Survey.*

If then a stream that is carrying its maximum burden changes its velocity, owing to a change of any of the numerous factors on which the latter depends, there must be a corresponding change of the combination of all these factors, and, in turn, a change in the volume of burden carried.

An important factor is found in the horizontal alignment of a channel, the carrying capacity being affected by turns and their curvature. The convex side of the stream suffers erosion, while the concave side, as a rule, shows the formation of a bank.

Tributaries produce a steeper slope after the point of confluence. An affluent brings in a quantity of material which the main stream, having its own burden to carry, cannot entirely absorb under the same grade. As a result, deposits may occur below the point of junction, until the river-bed is raised and the velocity increased to such an extent as to take care of all sediment. Upon last analysis it is found that the ruling element is that of the slope.

Careful study of the old river channels will often disclose the very important fact that, in almost every one of the differing sections, stretches may be found where the river is in a state of equilibrium, neither attacking banks, overflowing, nor depositing, and scouring its bottom only during extreme high floods. Particular attention should be paid to such portions of the river-bed, and all its properties ascertained, such as geological formation, character of the banks, slope of banks, their vegetation, grade of the river-bed, its cross-section, horizontal alignment, and the character of the débris. In the writer's opinion, these properties must form the basis for the solution of the problem at hand. Nature often will indicate what type of channel will best serve the purpose.

In the discussion which follows reference is made by way of example to the San Gabriel River as being a characteristic normal stream, and one of the most important in Southern California. It has a water-shed above the mouth of its canyon of 222 sq. miles, and a flood peak exceeding 30 000 sec-ft.

Every one of the larger rivers exhibits at least the following characteristics:

1. A mountain section, in which stream action is erosional, this section being defined as extending from the source of the stream to the mouth of the canyon.

2. A débris cone, extending from the mouth of the canyon as far as river action is alluvial.

3. A valley section, beginning at the foot of the débris cone, where river action becomes erosional. This district, as far as the tidal rivers are concerned, may be defined as extending to the delta, while with intercepting streams it would reach to the point of junction with the main stream. River action in the valley section, as a rule, starts with erosion. A few miles below, it may turn into alluvial action, then back to erosional, and again to alluvial. The alternation is apparently more frequent in the smaller than in the larger streams.

4. A delta section, which is the last alluvial sector, and terminates at tide-water.

Description of Characteristics of Individual Sections.

The Mountain Section.—The mountain ranges of Southern California rise from 1 000 to 10 000 ft. above sea level. The foot-hill region along the line where canyons debouch into the valleys, is about at an elevation of 1 000 ft. By far the greatest portion of the mountainous area is below Elevation 6 000. As far as the San Gabriel, San Bernardino, and San Jacinto blocks are concerned, the formation is granitic and metamorphic, including gneisses and schists. The outlying hills are either shale or old alluvial formation. An exception to this rule is found in the Santa Monica and Ventura Mountains, which are sedimentary.

As a rule the mountains are covered either with dense brush or timber. The lower timber line is at 5 000 ft. Invariably, it is found that slopes dipping to the north have a better forest cover than those more directly exposed to the rays of the sun. A shady slope shows a thicker crust of earth than a sunny one. The absence of a brush cover exposes the slope to washing, leaving often only a thin crust of earth overlying bed-rock.

The grades of the mountain sides are very steep, slopes of 2 000 ft. per mile being common; consequently, the stream beds of the side canyons, which may be called primary creeks, are equally steep. These primary streams generally flow on bed-rock, often along fault lines, and in narrow gorges. The action of the floods keeps these gorges well scoured. It is believed that the quantity of débris transported by individual primary canyons is comparatively small. The

writer has, however, no specific data to offer in support of this opinion, and reliable information on the subject is much needed.

The steep primary canyons, as a rule, discharge into a collecting channel of much flatter grade. Always a short distance below the point of a junction is to be found a deposit of débris, which is really the débris cone of the primary channel. Since primary channels, as a rule, follow in rapid succession, it is found that the intercepting channel presents a comparatively wide bed of deposits of large boulders, gravel, and sand along its entire length.

In order to make this description more tangible, reference is made to the West Fork of the San Gabriel River. This fork issues from San Gabriel peak, with an elevation of 6 152 ft., as a primary creek for about 1½ miles, and drops to an elevation of 3 500 ft., where it assumes the rôle of an intercepting channel.

The general course of the West Fork is easterly, intercepting numerous primary channels, and some minor intercepting channels from both the north and south sides. The length of the intercepting channel is about 14 miles, and the drop 2 200 ft., to the junction with the East Fork of the San Gabriel River, at an elevation of 1 360 ft. The primary tributaries intercepted by the West Fork have an average grade of 2 000 ft. to the mile, while the intercepting channel itself averages 160 ft. to the mile. From the junction of the West and East Forks to the mouth of the canyon at Azusa, the distance is 9 miles, and the drop about 600 ft. Although it is quite clear that the primary channels are under the constant action of erosive forces, it would appear that the secondary or intercepting channel remains more or less in a state of equilibrium. During each flood, primary channels will bring certain quantities of débris into the valley, and these, in turn, are carried on during the flood, with the result that, over a period of years, these intercepting channels remain about the same, showing neither permanent cutting nor alluvial action. This fact should be remembered in the discussion of the effect of check dams; because should the transportation of the coarse débris from a primary to an intercepting channel be stopped, the stream, when reaching the latter, would have a capacity to load itself with a new burden, and would begin erosion until a flatter grade had been formed and a new state of equilibrium established.

Attention is called to another fact—the comparatively short length and low drop of an intercepting channel, as compared with the sum of the lengths and drops of the primary channels which feed it. The difference is particularly striking in the drop, which may be only one-twentieth of that of the primary channels. These facts should receive attention in considering the feasibility of constructing check dams over an entire water-shed. If it is simply desired to arrest the transportation of débris, it might be done at less expense in the intercepting channel than in its primary tributaries.

The canyons, while all steep, do not all have the characteristics of highly erosional channels. Canyons filled with large deposits of alluvial materials, particularly of old alluvium, are frequent. These deposits are well consolidated, are covered with brush and timber, and apparently absorb a large proportion of the rainfall, even during periods of heavy freshets. They invariably produce, comparatively speaking, a prolific summer flow. Their stream beds indicate that flood discharge occurs in a moderate volume, as compared with canyons which may be immediately adjoining, and which have all the markings of wild storm channels. Apparently, in these canyons, Nature has produced what man is trying to accomplish, and for this reason they should be studied in solving problems of river improvement.

Summarizing the characteristics of the mountain section, it may be stated that it has the steepest grades, the most rapid run-off, the highest velocities, and last, but not least, it is the original source of all débris.

As the disintegration of rocks and the formation of débris cannot be checked, there remains the prevention of its transportation into the valley below.

The Débris Cone.—Below the mouth of a canyon, grades become flatter, and the coarser débris brought down from the mountain section is deposited in fan-shaped areas, commonly called débris cones, and here defined as extending from the mouth of the canyon as far down stream as action is alluvial. Erosional action and the transportation of detrital matter in the mountain section may be defined, therefore, as the "cause", and the formation of the débris cone as the "effect."

The channel on a débris cone is, as a rule, a pronounced cut, not always entirely straight, but not materially deviating from the line

of steepest grade. A slight shifting at the apex, however, may cause the stream to follow an entirely new path, although still along a line of steepest gradient. It is a fact that the San Gabriel River at Azusa might find a channel either side of its present course. In either case, it would invade a large area now in a high state of cultivation.

In the very nature of things, it is difficult, if not impossible, to maintain a stream on the débris cone permanently in the same channel. Fig. 2, compiled from data contained in the Los Angeles County Flood Control Report of January 2d, 1917, represents a cross-section through the débris cone 4 miles below Azusa.

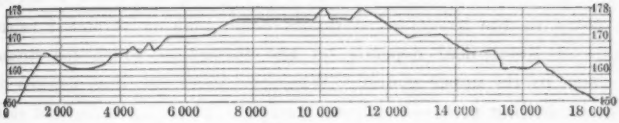

FIG. 2.

The cone covers a roughly triangular area, with its apex at the mouth of the canyon at Azusa at an elevation of 750 ft., and with a base about 3 miles wide at a distance of 6 miles below Azusa. The débris at the apex varies from large boulders, weighing several tons, to coarse gravels, while at the base the largest boulders may average 200 lb. At the base (Elevation 350), the river divides into two channels, the Rio Hondo, flowing southwest, and the East San Gabriel, flowing south. At present, by far the largest portion of a flood finds its way into the Rio Hondo.

On the débris cone much seepage occurs into the underlying gravel beds, particularly during heavy storms. The percentage of seepage increases as the débris becomes smaller and more uniform in size. The writer's experience has shown that an aggregate, such as is generally used for concreting, presents an excellent seepage bed, while large boulders and coarse gravel reduce the percentage of absorbing voids. Still better results are obtained with fine sands, but they are not always to be found on the cone. The water-plane under a débris cone is, as a rule, at considerable depth, from 100 to 200 ft. or more below the surface; so that storage basins of large capacity are often available.

During the peak of floods the quantity of silt in suspension is large, and such muddy water is not absorbed. It has become the practice in artificial spreading works not to divert any water during the

first day or two of a flood, so as to eliminate the muddy water which would silt up the pores of the gravel beds. If, therefore, artificial absorption is practiced to reduce a peak load, the first requisite will be a material reduction in the quantity of silt in suspension. The greatest difficulty so far encountered with unimproved streams, however, is the instability of the channel on the cone and the danger of causing diversions, for which the manipulator would be responsible.

The action of a heavy flood in most channels is to tear up the stream bed and produce temporary scouring. Subsequently, during the receding of the river, the scoured bed is refilled. Since streams always carry some silt, the effect of a receding stream is to silt up the pores in the gravel of a débris cone, making it almost water-tight. A great deal depends on the formation which the stream traverses in its upper course. Wherever there are lime deposits or clay, the sealing process is almost perfect. The best example of such silting is probably the Whitewater River near Banning, which most of the time has a milky appearance from the silt it carries, which silt is extremely effective in sealing the pores after the winter floods.

It is essential, if the natural seepage is to be maintained, that floods should occur, which will tear up the river-bed and re-open the pores. The tearing-up process is the most important function of a flood and furthers natural absorption.

The changes in the course of a stream on its débris cone presents a criterion from which conclusions might be drawn as to the quantity of débris produced in the mountain section. No information has come to the writer's knowledge that either the San Gabriel River or the Santa Ana River has materially changed its course during the last 60 years.

The improvement contemplated by the Los Angeles County Flood Control District for the San Gabriel River cone is described in its Report of 1917, page 29, as follows:

"The work required is the excavation of a channel 400 ft. wide and 4 ft. deep to form a minor or interior channel. The material from this excavated channel is to be placed in levees upon either side of the channel, and at a distance varying from 600 ft. to ½ mile, as shown upon the Plate. This boulder material is to form levees which will be 12 ft. wide on top, the slope on the water side will be 3 horizontal to 1 vertical, and upon the back or land side will be 1½

horizontal to 1 vertical; the elevation of the tops of these levees to be 18 ft. above the bottom of the minor or interior channel. This minor channel will provide for the carrying of ordinary floods, say, up to 20 000 sec-ft., while when the great floods of 40 000 or 50 000 cu. ft. per sec. come, the entire area between levees amounting to 2 500 acres will be flooded, thereby providing a large spreading ground. This design of a minor and major channel will have a tendency to hold the principal thread of the main current near the center of the minor or deeper channel, and thereby reduce the velocities near the levees, on the whole having a tendency to arrest velocity and precipitate the detritus, and to cause as much of the flow as possible to percolate and reach the artesian water through the coarse materials at the head of the valley. * * *

"* * * It should now be distinctly understood that the plan of the channel here outlined, and, for that matter, any other channel in a detrital country, will require examination and correction after every flood. Great floods coming out of the San Gabriel canyon always, when at peak, bring great loads of detrital matter which are dropped by a very sensitive natural law as the velocity or carrying power of the stream weakens with every slight reduction of the gradient, and a heavy part may be dropped by one storm a short distance down this very large channel, while the next flood wave being larger or smaller, may drop its load farther down, or higher up. This condition must be watched with a vigilant eye and removed so thoroughly after each storm as to bring both the minor or interior channel and the larger or major channel to a carrying capacity. If this maintenance is neglected, disaster will follow."

Effective control of floods on the débris cone requires, first, that the stream arrive at the mouth of the canyon delivered of its rolling débris; second, that the stream be prevented from resuming erosive action on its way down the cone; third, that the stream arrive at the mouth of the canyon delivered of the larger portion of its sediments in suspension; and fourth, that means be provided to induce the seepage into the ground of a large percentage of the flood flow, particularly of the peak load.

The Valley Section.—A stream, having delivered itself on the débris cone of its burden of coarse detritus, such as boulders, large gravel, and coarse sand, has a scouring capacity from the point where it leaves the cone, and, therefore, will produce a stream-bed in cut. Proceeding down stream the cut gradually becomes shallower and a

deposit of sediment takes place. With most rivers there occurs in the valley section a succession of erosional and alluvial stream activity.

A channel in cut has a more or less rectangular cross-section, sometimes with well-developed berms. The formation in the valley districts is an alluvium, consisting of gravelly or sandy loam, which becomes finer with lower elevations, constituting river banks that readily succumb to scouring action under high velocities. The floor of a channel consists of different materials than the banks. The high flood velocities of a cutting stream have a distinct scouring effect on the bottom, and the materials forming it are, during the flood flow, in motion to great depth. A large quantity of sand and silt, therefore, is liberated and set in motion, which ultimately will be laid down where grades become flatter and velocities lower. This débris in traction undergoes a natural process of assortment, the heavier sinking while the lighter remains near the top, with the silt floating off in suspension. A test hole in a river-bed would show a fairly well assorted deposit, ranging from sand on the surface to gravel and small boulders at greater depth. As the flood recedes the bed is refilled, and over a series of years its profile and depth remain about the same.

From observations on the Santa Ana River by Mr. G. O. Newman in 1892, it was concluded that the deposits forming the bed at the point of observation were in motion during flood to a depth of at least 15 ft.

The volume of débris liberated and moved on account of erosion of the channel floor is many times greater than that produced by washing of banks. Scour of the channel floor is at its height during the peak flow, while undermining of banks is, as a rule, more pronounced during a protracted receding flood, as previously mentioned. The damage in an erosional section is caused by undermining of the banks, not by overflow.

The effect of the erosional action and the loading of a river becomes manifest proceeding down stream under a flattening gradient. The channel becomes gradually shallower and the stream drops its débris and eventually overflows its banks. This process is sometimes so pronounced as to produce a secondary débris cone with its characteristic steepest gradients along lines running through its apex. An example is to be found in the Los Angeles River which, some years ago, had its course from Fruitland south, passing between Bell

Station and Huntington Park, while to-day it flows from the apex of its secondary débris cone at Fruitland in a southeast direction, passing east of Bell Station.

As a rule there is a pronounced small channel in these alluvial sectors.

Fig. 5 is a cross-section of the Rio Hondo at the Stewart and Gray Road, just below Downey, where the river begins to overflow. The

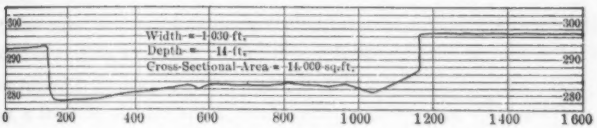

FIG. 3.

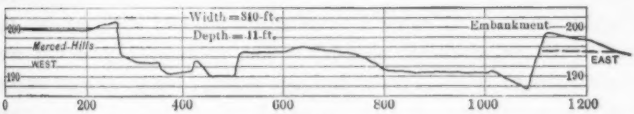

FIG. 4.

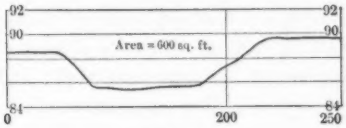

FIG. 5.

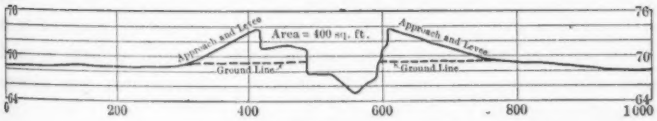

FIG. 6.

cross-sectional area is 600 sq. ft. as compared with 14 000 sq. ft. at Pomona Boulevard, as shown on Fig. 3. (See also Fig. 6.)

Below an alluvial section there invariably follows an erosional one, and *vice versa*, until the stream is absorbed by a larger one or enters its delta. For the Rio Hondo the last erosional sector is located between Downey and Dominguez, below the junction with the Los Angeles River. The slower velocities in an alluvial or inundated section are favorable for the absorption of flood-water, provided the

water is reasonably clear and the water-plane at some depth below the surface.

It would appear rational to assume that after a long period of years a stream would change its activity in a locality from alluvial to erosional, and *vice versa*.

There is a wide difference in the character and volume of flood flow from forested or brush-covered mountainous water-sheds, as compared with urban or interurban drainage areas. Drainage channels issuing from the latter have no débris cone and move a large quantity of detrital matter into the valley section. The effect of this is noticeable particularly during a series of years of moderate or deficient rainfall. Years may pass without the heavy rains which produce a moderate flood run-off in the mountains, while occasional short but intense showers may cause a flashy run-off from city and interurban streets, of sufficient force to carry a considerable load of sediment into the smaller natural drainage channels. The volume of flood flow may be sufficient to reach a main drainage artery; being without support from the mountains, it may not reach tide-water, but slowly seeps away. It also occurs that a flood flow may be of such short duration that it will not pass beyond a minor branch channel.

However, in each case, there will be a deposit of detrital matter, at least along portions of secondary channels, and sometimes over portions of a main channel. The cumulative effect over a period of years of such stream activity is a partial filling up of the affected river-beds, with the result that they are not in shape to take care of a sudden exceptional flood. The remedy commonly resorted to is to provide a compound cross-section with a small central channel and wide berms. In order to be effective, however, this type of construction must be carried clear to the sea.

The present methods of improvement in the valley section are bank protection by pile and wire entanglement for erosional river-beds, and levees for alluvial ones. No attempt has been made with larger streams to check bottom erosion by the introduction of fixed sills.

A peculiar feature of the valley zones are the "narrows" which form what might be called fixed points in the valley course of a river, where the river must pass regardless of what action might take place in its course above or below. The effect of narrows is mani-

fested not only on the surface streams, but also on the underflow, in that the contraction of the valley brings the underflow to the surface, and produces artesian or rising streams and artesian flow in cased wells.

Reviewing the characteristics of the valley section, it is found that the flood channels appear as alternation of erosional channels and more or less pronounced alluvial cones. The stream reaches the valley section with a capacity to increase its burden, and invariably leaves it with a full load. Damage is caused by the washing of banks in erosional channels, and by inundation in alluvial ones.

River control in the valley section requires the prevention of erosion and the transportation of detrital matter, alternating with protection from inundation, with the ultimate purpose of delivering at the delta a stream free from débris in traction, and clear of the major portion of its sediments in suspension. Improvements on the débris cone and in the mountain section above, unless resulting in a reduction of volume of stream flow, are of no material beneficial effect in the valley section. In fact, an attempt to clarify the stream and to deliver clear water into the valley section would be positively injurious, unless accompanied by the introduction of flatter gradients.

Exceptional as well as small flood discharge must be taken into consideration, and particularly the cumulative effect of exclusively moderate or small flood flow over a series of years.

The Delta Section.—In the delta section, grades continue to flatten down to such an extent that the action of the river becomes alluvial, building up a cone of sand and silt. As a rule, the stream channel is quite shallow and of small carrying capacity, so that even ordinary floods produce inundations. Shifting of the channel occurs more frequently than on the débris cone. A single flood may produce deposits over large areas, of 1 ft. or more, as has occurred near Long Beach during the floods of the Rio Hondo-Los Angeles River.

For this river the delta starts at Dominguez at an elevation of 50 ft., about 10 miles from tide-water, with a grade of 7 ft. to the mile, while in the vicinity of tide-water it falls to 2 ft. per mile. Fig. 7 gives a cross-section of the delta between the Dominguez and Long Beach Mesas. It will be noticed that the country is flat and that there is no pronounced channel of large capacity. This area has been inundated during heavy floods over its entire width.

If natural conditions, such as grades, volume of flow, and silt, would permit a solution of the problem in the delta district, stretches would be found where the stream-bed is in a state of stable equilibrium, and such stretches would indicate the grades and character of channel required. In a typical delta, the writer has nowhere found such conditions.

At the estuaries of streams are found almost invariably large tidal flats, often with a considerable number of tidal channels and lagoons. The banks of the tide flats are about at the elevation of high tide, between 5 and 6 ft. above mean low water. Where the area occupied by the tidal channels and lagoons is of considerable extent, so as to produce a tidal prism of some magnitude, the estuary is open all the year round, regardless of the fact that the rivers dry up in summer, as, for example, at Alamitos Bay, Newport Beach, Playa del Rey, and Long Beach. In many streams, however, the tidal prism is not sufficiently large, and breaker action closes the estuary soon after

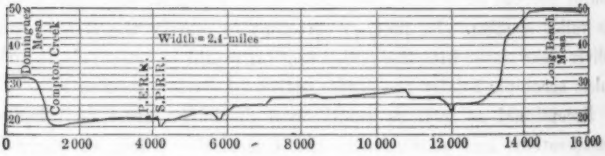

FIG. 7.

the winter floods, to remain in this condition until the next flood. These conditions are observed at Santa Barbara, at Hueneme, and in many estuaries of the minor rivers.

The average rise of tide in Southern California is between 5 and 6 ft., the maximum being between 8 and 9 ft.

There is a strong littoral current along the coast of Southern California, running in a southeast direction. Its effect has been to shift the mouths of the streams down coast, there being a constant scouring action on the south side of the estuary. This has come to the writer's notice particularly at Long Beach. Some of the older coast survey maps which show the estuary at Long Beach, show the outlet about ¼ mile west of the present lift-bridge of the Salt Lake Railroad. When in the early Nineties, the Los Angeles Terminal Railway, now the Salt Lake Railroad, built its trestle across the estuary, it was found difficult to prevent the scouring of the eastern

embankment, and many carloads of boulders and scrap iron were dumped to consolidate the east bank at the crossing. The bridge was about 500 ft. inland from the high tide line. However, the littoral current was strong enough to produce a deflection along the beach, as shown in Fig. 8.

The deflection of an estuary continues until checked by a resisting formation, like the shale hills of Playa del Rey, or the clay mesas of Seal Beach, Huntington Beach, and Manhattan Beach.

If it happens that a flood is great enough to cut through the sand spit at its land end, a direct outlet into the ocean will be established

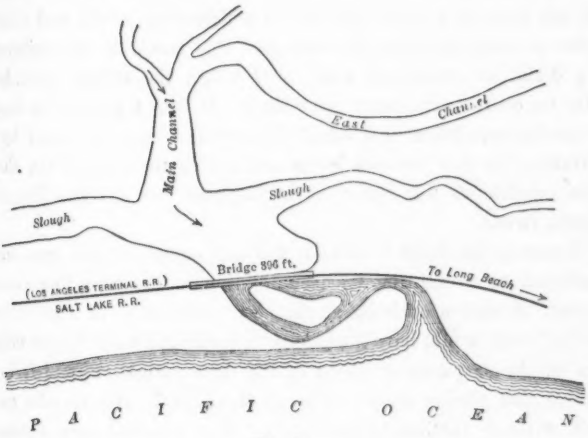

FIG. 8.

along the lines of steepest grade, as occurred with the Santa Ana River during the flood of 1916, when it abandoned Newport Beach lagoon and estuary, and cut a direct channel to the beach about 2 miles west of the estuary.

After such a direct outlet is cut, the littoral current immediately resumes its action tending to shift the estuary again to the south. Eventually, the effect will be a gradual obliteration of the old sand-spit and the formation of a new one in the wake of the shifting estuary.

An example of a river the delta of which begins only at tide-water, is the Santa Clara in Ventura County. The peculiarity of this river is

that from Santa Paula to tide-water, or a distance of 16 miles, the grade changes very slightly, namely, from 16.7 ft. to 13.5 ft. per mile. As a consequence, the river is in cut practically to the beach. At the State Highway bridge near El Rio, about half way between Ventura and Oxnard, and 4½ miles from tide-water, the river runs still in a well pronounced cut, at an elevation of 62 ft. above sea level. Charles W. Petit, Assoc. M. Am. Soc. C. E., County Engineer of Ventura County, has stated that the elevation of the river bottom at the bridge did not change at all between 1896 and 1912. The problem on the lower Santa Clara River is, therefore, clearly one of bank protection.

Summarizing conditions in the delta section, it may be stated that they are those of a river running on a flattening grade, and therefore unable to carry its load of sediment. The result is the building up of a delta, or sedimental cone, over which the stream spreads and shifts its course with every large flood. It is not possible to improve the general condition of grades. Some relief may be gained by concentrating the flow between levees and giving the channel the shortest route possible to tide-water, as is proposed for the Rio Hondo-Los Angeles River.

However, the basic trouble is the sediment, and this can only be eliminated by preventing its accumulation in the preceding erosional section. A stream arriving at the head of its delta in a more or less clarified state, would have a capacity to erode and cut a deeper channel, even on the flattening gradient of the delta formation, and it is conceivable that during moderate floods it might be able to take care of itself without further improvement. For extraordinary floods, the inundation area should be defined by levees and its use for residential or industrial purposes prevented.

The littoral current which, in this section of the coast, tends to deflect an estuary in a southeast direction, will exercise a marked influence on the land water flood problems.

DISCUSSION

Mr. Pohl.

CHARLES A. POHL,* M. AM. SOC. C. E.—Attention is called, on page 1128 of the paper, to observations by Mr. G. O. Newman, in 1892, on the Santa Ana River, which show that deposits in the river bed were in motion to a depth of 15 ft.

Observations on other rivers show that scour of the river bed may extend to even greater depths. In a report by the late James B. Eads, F. Am. Soc. C. E., on the St. Louis Bridge, he states:

"Soundings made by me prove that this deposit is scoured out to a great depth in time of floods and freshets. Although I have not had any extreme stage of water in which to make my observations, I found that a rise 13 ft. less than high-water mark caused a scour of 18 ft. The greatest variation in the height of the river known at this place is about 41 ft. * * * The concentration into this narrow channel of the vast volumes that are sometimes poured out of the gigantic net-work of streams above St. Louis, the main artery alone of which is navigable over a thousand leagues above this city, assures me that in time of floods it is not improbable that this deposit is removed to twice or thrice the depth shown by my soundings, and perhaps to the rock itself."

The rock under the westerly pier of the Eads Bridge is 55 ft. below high water; under the second pier, it is 99 ft., under the third, 127 ft., and under the fourth pier, at the easterly side of the channel, 135 ft. below high water. At the center of the middle span, the low-water depth of the river was about 15 ft., and the depth from the river bed at the same point to rock at low-water stage was 60 ft. Under the center of the easterly span, the low-water depth was 15 ft. and the depth from the river bed to rock about 80 ft. As Capt. Eads' observations were made presumably at the bridge site, they would indicate a scour of four and possibly five times the low-water channel depth.

The extent of the erosion of the banks and bed of the Mississippi River is enormous. The following data are taken from a Report by a Special Board of Engineers on Survey of Mississippi River:†

"Similar measurements were made during the present year (1908-09) as to the extent of caving banks on the river between Cairo and St. Louis, by which it was shown that the volume of earth falling into the river from that reach averaged annually 64 000 000 cu. yd. from 1879-1889; nearly 48 000 000 cu. yd. from 1889-1899; and about 49 500 000 cu. yd. from 1899-1907, the diminution of such caving in the last eighteen years evidenced thereby being considered due to the extensive revetments that were built along this reach between 1881 and 1905.

* New York City.

† Document No. 50, 61st Congress, 1st Session.

Mr. Pohl. "AVERAGE ANNUAL AMOUNT OF CAVING ON BOTH BANKS, MISSISSIPPI RIVER, CAIRO TO DONALDSONVILLE.

Locality.	AREA.	HEIGHT FROM RIVER BOTTOM TO TOP OF BANK.
	Square yards.	Feet.
Cairo to Memphis	6 112 000	53
Memphis to Helena	2 978 000	47
Helena to Arkansas City	4 137 000	62
Arkansas City to Vicksburg	12 024 000	67
Vicksburg to Natchez	9 371 000	76
Natchez to Red River	3 106 000	78
Red River to Donaldsonville	1 263 000	84
Total	38 991 000	66*

* Annual average.

* * * * * *

"Experiments conducted in 1879 under the direction of the St. Louis U. S. Engineer Department at the mouth of the Missouri River to determine the amount of sediment coming into the Mississippi River from the Missouri above St. Louis (p. 1653, Annual Report, Chief of Engineers, 1881, and p. 3090, Annual Report, Chief of Engineers, 1887), showed that the floating sediment alone, resulting from caving banks in the Missouri itself, amounted to 187 000 000 cu. yd. during nine months of the year. As these observations took no account of the heavier matter in the foot of depth nearest the bottom, nor of the solid material (such as sand or gravel) driven along the actual bed of the river by its currents, Col. Suter considered it safe to assume that fully 400 000 000 cu. yd. of material then came out of the Missouri River in twelve months. It is probable that at least the same amount of material is still coming out of the Missouri River at the present time. Other observations by the U. S. Engineer Department and the Mississippi River Commission indicate an outflow of sediment and rolling material of about 36 000 000 cu. yd. per year from the Ohio River, about 5 000 000 cu. yd. per year from the Arkansas River and about 6 000 000 cu. yd. per year from the Red River.

"By the above showing, the amount of material originating from caving banks which the Mississippi River, between St. Louis and permanently deep water in the river below Donaldsonville, must carry along and dispose of every year, amounts to more than one and one-fourth billion cubic yards."

One of the factors in the adverse report by a Special Board of Engineers on the improvement of the Mississippi River between St. Louis and Cairo, by means of two large dams—one at Jefferson Barracks just below St. Louis, and the other near the Thebes Bridge, about 40 miles above Cairo—was that the filling up of the pools above the dams would inevitably take place.

Mr. Pohl.

An estimate was made by the Board that dredging of from 100 000 000 to 400 000 000 cu. yd. of material would be required each year to prevent the filling up of the channel above the dams and the floods and other damage resulting therefrom.

The Tennessee River does not carry a heavy load of silt. Its banks are very stable, and very little caving and erosion occur along the main stream which has a length of about 215 miles above the Hales Bar Dam, near Chattanooga, to the head of navigation at Knoxville, and a drainage area of about 29 000 sq. miles at the dam. The material carried is nearly all in suspension and presumably comes from the smaller tributaries 100 miles or more.

In 1918, fields of corn were under cultivation above this dam on land which was under low water when the dam was completed in 1913.

The raising of the river bed by several feet in 5 years shows what may be expected where the velocity of a river carrying soil in suspension is lessened by the construction of a large dam.

Mr. Wright.

FRANCIS H. WRIGHT,* ASSOC. M. AM. SOC. C. E.—The losses caused by erosion along the Mississippi River are something which erosion has also built up again, that is, the eroded material becomes alluvial as it is restored by deposit along the lower reaches. The speaker does not believe that, if the quantity of eroded material is set against the quantity restored along the lower river, any great change will be found in the adjacent geology within the span of a life time. He believes that the great quantity that is carried out of the mouth of the Mississippi is that which originally came from the upper reaches of the Missouri River, or from the Ohio River, especially the former.

The gradient of a stream near its source in the hills begins as a convex curve which gradually changes and becomes concave, ending in a tangent at its base or at sea level. The convex gradient is one of irregular steep slopes making rapid velocity, with great scouring and conveying capacity. The concave gradient of more uniform slopes is characterized by their flattening with approach to base level, with reduction in the average velocity, and tendency of the stream to deposit its burden. This tendency is apparent immediately following periods of flood.

The section of a stream within and below the elevation of what is commonly known as "bank full" stage can be defined as a normal section. Equal velocities through equal sections will convey equal volumes in equal periods of time. Variations in velocity, however, do not function with variations that exist in the normal section and the volume of discharge of a stream. The normal section along the concave gradient becomes abnormal during flood, through the overflow, and the previously mentioned variables are thereby harmonized.

* New York City.

Mr. Wright.

Unless confined, the section becomes greatly increased, with a consequent reduction in the average velocity and carrying capacity. Subsidence brings a further reduction in velocity, and the stream returns to its normal section within its banks. These reductions in velocity at a time when the stream is most charged with suspended matter, show the greatest amount of deposit. This is especially apparent over the overflowed area just after subsidence. The removal of material from along the upper reaches of a stream to its deposit along the lower reaches is a natural result from the character and variation in its gradient. The Mississippi being very flat and alluvial in its delta region, it follows that its gradient at that point is a concave curve.

The condition described in Mr. Sonderegger's paper, as the speaker has been able to understand it, is a more difficult problem of flood control than that of the Mississippi, even though of lesser magnitude.

These Southern California rivers pass suddenly from steep slopes in rock-lined canyons through débris cones of unknown density and doubtful stability to an alluvial valley with flat slopes. These cones, accumulated through ages, are located where the stream section readily becomes abnormal and where the velocity suddenly decreases.

Among the requirements which the author considers as the solution of this problem is that of absorption on the débris cone of the peak flood load. This implies the use of storage reservoirs. The speaker can imagine that it would be quite difficult to hold this water on these cones. It appears possible for it to escape, not only through absorption, but by breaking through the cone at some lower elevation and seeking a new channel to the sea. If the escape is only through absorption within the débris cone, the seepage arising therefrom in the lower valley would have to be considered.

Some of the effects of high water which the speaker has observed along the Lower Mississippi have led him to believe that full storage reservoirs would cause all the adjacent soil to become saturated. A continued rainy period, added to a full reservoir, would furnish more potential danger than without the reservoirs.

With reference to the previous remarks about the erosion along the Lower Mississippi, the speaker does not wish to convey the impression that he considers it as insignificant. It is very great, but it is balanced by the replacement which is also very great. During the past ages, the latter has exceeded the former, or there would be no alluvial valley to-day. The sum total of material that passes the mouth of the Mississippi River into the Gulf of Mexico will balance the quantity derived from the region tributary to the convex gradient of that river or its feeders, less the increment in the lower alluvial valley.

Mr. Wright.

As to actual erosion, one instance is recalled where a plantation (the Bondurant Plantation in Tensas Parish), in Louisiana lost nearly 1 700 ft. of receding caving bank during one year. This distance was taken along a line at right angles to the axis of the channel at that place and was measured from actual surveys. A few miles down stream, a sand-bar was built up, which was probably of sufficient volume to offset that which was taken from this plantation. That which is taken from one side is restored on the opposite side, etc. The silt is deposited, picked up, carried farther, again deposited, etc., during the different years of its journey from its origin to its final deposit or to the sea.

J. A. Ockerson, Past-President, Am. Soc. C. E., has made a report* concerning surveys undertaken to estimate the amount of erosion through caving banks along the Mississippi River. These surveys were made in 1891-92 along caving bends between Cairo, Ill., and Donaldsonville, La. The survey of 1879 of the Mississippi River Commission between Cairo and the Passes was a thorough topographical and hydrographical survey which included the areas resurveyed, and an accurate estimate was made from the sections produced between the two surveys.

The estimate given in that report shows that the annual erosion between Cairo and Donaldsonville amounts to a volume 66 ft. in depth, over an area of 9½ acres for each mile of river, or, for the total length of river included by the survey, a volume of 86 ft. in depth over 10 sq. miles of area. This estimate only refers to the quantity eroded and makes no allowance for quantities deposited on banks or in the channel.

Mr. Ockerson mentions a fill near Commerce, Mo., about 2 000 ft. wide and about 5 miles long, which was under cultivation at that time (1891), but which, in 1879, was occupied by the river and outside of a caving bank. The large quantity of erosion referred to in Mr. Ockerson's report might have originally started in Wyoming or Montana and probably required some hundred years to reach the Lower Mississippi, perhaps less, but a long time.

It is said that, in the distant past, the mouth of the Mississippi River was at about the present location of Cairo, Ill., and that there it entered the Gulf of Mexico. The region to the south, which is commonly known as the delta, has been built up through alluvial deposits since that time.

The construction of a concrete warehouse for an unloading wharf on the Mississippi River, on which the speaker was engaged, required pile clusters, heavily loaded, to support the concrete footings. A sheet-piling enclosure surrounded the site, and after the clusters were driven, a sand filling was pumped in, surrounding the clusters to the

* Annual Report of the Chief of Engineers, U. S. A., 1892, Pt. 4, p. 3111.

Mr. Wright.

elevation of the bottom of the concrete footings, and serving as a base for them during construction. At extreme low water, or while the sump pumps were active, a crust formed over this fill, which was able to carry a heavy load and on which one could walk. A 70-ft. pile dropping from the driver leads would not "take up" for 30 or 40 ft. in the silt below. Piling in place and projecting 5 or 6 ft. above the crust vibrated very perceptibly from a good lusty kick. This sand filling had been placed during an interval of perhaps two years from the placing of these piling clusters until it was practicable to pour the concrete footings.

In checking the positions of the piles in the clusters for errors in their centers of gravity and their correction, the speaker observed that many of them were much inclined from the perpendicular and symmetrical in the amount of their inclination and in its general direction. It was surprising to discover that the pitch from the perpendicular of some of the piling was 3 in. and more to the foot of length, or a lean in a 70-ft. pile of about 18 ft. It was realized that the design load could not be applied under these conditions, as the piling would bend through the soft silt to complete failure. A careful survey was made with a plumb and rule, and those piles which deviated beyond the adopted limit were cut out and others driven. The symmetrical inclination was attributed to a movement of the sand filling toward the channel of the river.

It is the speaker's opinion that movement of a culvert is possible through inclined piling in a soft soil. Inclined piling has been driven and properly capped to receive thrusts without bending in the piles and has been satisfactory. Where compensation against bending is not provided, or cannot be given, the consequences are apt to be uncomfortable to say the least.

Mr. Dunham.

H. F. DUNHAM,* M. AM. SOC. C. E.—The profile of the Susquehanna River could be cited as being unlike any of the profiles referred to by the author. The grades coincide or are approximately regular until the flattening out would indicate a near approach to sea level, and then the river drops more than 200 ft. in about 40 miles, or a comparatively short distance. This occurs in a region where uplifts and vibrations are rare instead of frequent. It has not been shown that the condition is due to glacial action.

Two or three statements in this interesting paper may seem worthy of further comment or of explanation by the author. His graphic description of débris cones is appreciated by the speaker who has had little opportunity to see them and none at all to study them. In ignorance, too, of California practice, any detail of the method used to determine the percentage of seepage at the higher or lower

* New York City.

Mr. Dunham.

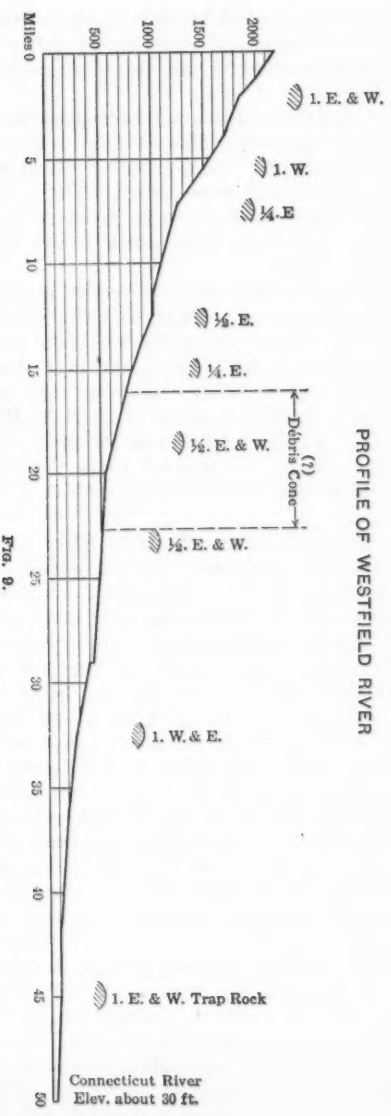

FIG. 9.

Mr. Dunham.

sections of a débris cone would be of interest to him, especially as the distance between the points of variation are well within ten miles, and the formation throughout is the result of moderately uniform natural causes.

Except for some subtle condition not understood, the speaker would say that the more an aggregate differed from one that ought to be used for concrete, the better seepage bed it would be where large additions to the ground-water were desired. The weight of the material composing the aggregate might be given in terms of specific gravity of the rock formations from which it was derived, whether in part volcanic ash or tufa.

On page 1127, requirements for the effective control of floods on the débris cone are mentioned. They comprise elimination of the rolling débris and the larger part of the suspended matter when the water reaches the mouth of the canyon; and it is also required that flood water so deprived of its burdens shall not take up new material or erode its bed and banks on a grade of 50 ft. to the mile. What agency can make this possible? Where on the steep slopes and mountain sides are reservoirs to be provided above the canyon for flood control? If provided, how quickly would they be filled with débris and become useless?

A section of the profile of the Westfield River, in Massachusetts, compares fairly well for grade with the débris-cone channel section (Fig. 2), shown by the author. The area above comprises about 90 sq. miles. Rocks, granite, gneiss, and mica schist are present; and a small quantity of slate is also present. The precipitation measures about 40 in. per annum, more nearly uniform per month, by the average of many years, than can be found in many sections of the United States. Downpours of 3 or 4 in. in 24 hours have been observed, and, in addition, there are heavy snows and thick ice, in the annual freshet period. At times of such floods, the depth of the water ranges from 15 to 20 ft., or more, above low water. The river flows over glacial deposits of boulder clay in many places. The river bed is never quite dry, but extremely few areas are covered with sand. At rare intervals there have been days when no current was visible. It is a river bed of stones, with boulders up to many tons in weight, and rather uniformly distributed, that is, big boulders are not appreciably more common or numerous at the upper than at the down-stream end of the cone section. The ice is a carrier, as it is often frozen to the boulders and stones, and more often bowls them along. At sharp turns in the channel, there may be depths of water of from 5 to 15 ft., measured from the low-water mark, and, in such holes, the scour at flood and the re-filling would be noticeable, but all within a very few feet; it might be nearer the truth to say a very few inches. Over or on the surface of the river bed, there is a slow

Mr. Dunham.

average movement of the stones and boulders down stream, but a movement of such material to a depth of 2 ft., or even 1 ft., below low-water mark, would be contrary to all observations unless it could be shown that at flood time the material at a depth of "15" ft. was moving down stream, while the river bed remained in place. If given in detail the observations of Mr. Newman, mentioned under "The Valley Section" (with a grade of 15 ft. per mile), should show some marked difference in the character of the material in California and New England, if the grades and moving agents were nearly identical.

With a rapidly increasing flow, water would find its way into the material of the river bed and banks or shores, and doubtless would exert pressures tending to keep that material in place. The pressure would be reversed when a flood-plain was quickly lowered, but at any time only a slight down-stream movement of the river bed can be expected and that over only limited areas.

A profile of the Westfield River (Fig. 9), shows a section which may correspond to that of the débris cone. A few adjacent summit elevations with distances from the river channel, in miles or fractions of miles, are shown. Thus, "½ E" shows the elevation of the ground ½ mile east of the river. The elevations are taken chiefly from U. S. Geological Survey quadrangles.

Mr. Bowlus.

FRED D. BOWLUS,* ASSOC. M. AM. SOC. C. E. (by letter).—The author mentions two important factors that put the flood-control problems of Southern California in a class by themselves; first, the uneven distribution of the rainfall, and second, the short distance from the mountain heights to the sea, with consequent steep gradients. Both contribute toward causing the erosion and transportation of enormous quantities of materials toward the ocean, which materials range from the finest silts to huge boulders.

A comprehensive study of the conditions affecting the transportation of these materials, as well as of the hydraulic properties of the existing channels, is of the utmost importance in the solution of flood-control problems. Without knowing these conditions, it is difficult to design a channel to carry a certain quantity of water, when the channel bed is of sand or gravel. During a flood, the bottom is scoured out, so that the channel carries very much more water than it is designed for, and as the flood recedes the channel bed is refilled with material. The depth of scour and of refill is difficult to determine.

Fig. 10 has been prepared to show the relative elevations of the water surface and of the average stream bed of the Colorado River at Yuma, Ariz., for four months of 1914. Generally, the floods occur on the Lower Colorado in June or early in July. The year 1914 represents an average of the floods for the past few years, the crest discharge being 137 000 sec-ft. Fig. 10 shows the gauge heights and

* San Francisco, Cal.

Mr. Bowlus.

mean depths. The top line represents the water surface, and the lower line the mean elevation of the stream bed. The discharge of the river is also indicated. It will be noted that the bed was lowered more than the water surface was raised during the period of the flood. The channel at the Yuma Station is somewhat confined, being between 500 and 600 ft. in width, and is thus illustrative of the conditions that would prevail with levees on flood-controlled streams. The drainage area of the Colorado River is about a thousand times greater than that of the San Gabriel, while the peak discharge is only four or five times larger. The duration of the flood, however, is much longer on the Colorado River. A study of the diagram shows that the erosion of the bed materials is gradual. More than 20 ft. in depth were eroded during this particular flood, all of which was replaced later. This represents the moving of about 1 000 000 cu. ft. of material to each 100-ft. station along the river bed. The extreme range

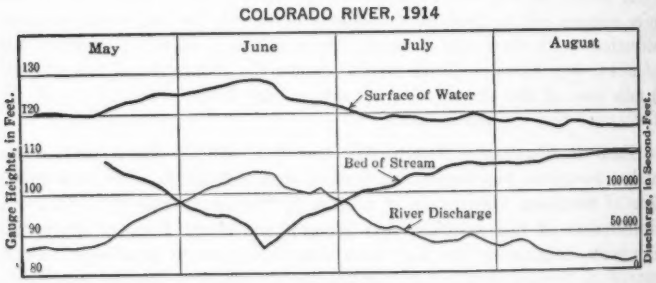

FIG. 10.

in the elevation of the river bed at Yuma is 40 ft. The mean velocity, at flood crest, never exceeds 7 or 8 ft. per sec., while, according to Mr. Ebert, of the U. S. Geological Survey, there have been peak velocities at the mouth of the San Gabriel River of from 20 to 25 ft. per sec.

Transportation of Débris.—The study of the transportation of débris is very complicated, because of the relationship between the various factors. Some valuable studies have been made by various hydraulic, sanitary, chemical, and mining engineers. Most of them, however, were for specific purposes, and their conclusions cannot be made of general application. The tests of Dr. G. K. Gilbert,* referred to by Mr. Sonderegger, were undertaken for a much broader purpose, but it is regretted that they were not completed as originally planned. All the sand used in Dr. Gilbert's tests was of a size greater than 50 mesh, consequently, conclusions are not directly applicable to the material that is found, for instance, in the Colorado River canals, all of which is finer than 80 mesh.

* *Professional Paper No. 86*, U. S. Geological Survey.

Mr. Bowlus.

It is generally recognized that there are three modes of transportation of silt. The finest particles are suspended throughout the entire cross-section somewhat like a solution, the medium grades are carried along just above the bottom of the stream by upward currents deflected from the bed, and the largest particles either slide, roll, or skip along the bottom.

No discussion of the many theories advanced for the cause of transportation by the first two methods will be undertaken at this time, the discussion being confined to the last named. In the course of engineering investigations with Mr. C. E. Tait, in the U. S. Department of Agriculture, in co-operation with the California State Department of Engineering, a study of the silt conditions along the Colorado River and the irrigation canals taking therefrom has been made. The Colorado River has been sampled when in flood, and very little material coarser than 100 mesh has been found except near the bed. Along the coastal streams of Southern California, gravel and boulders are transported from the mountains several miles out on to the débris cone.

Carrying Capacity of a Stream.—The transportation of débris by a stream is a tax on its energy. The stream can carry more fine than coarse material. Its carrying capacity has to do with the quantity of load and its weight per unit of water. Experiments have been made to determine the relation between capacity and mean velocity. Deacon* used a glass trough and found that the weight varied, approximately, as the fifth power of the mean velocity. Blue† used a small metal trough and found the variation to be about as the sixth power. It is obvious that these smooth troughs do not represent the conditions found in stream beds composed of sand and gravel.

Many determinations of the silt load per foot-width in canals along the Colorado River have been made by the California State Department of Engineering by taking samples of water at many different points in the cross-section of a canal or stream. That the load increases with the mean velocity is clear, but the exact relation has not been definitely fixed.

Size of Material Carried.—The mass, weight, or size of any individual particle that can just be moved by any given mean velocity (or preferably in terms of bed velocity) differs from, but is often confused with, capacity. It is said, in a loose way, that the quantity of material transported varies with the sixth power of the mean velocity. As a law, this refers to the mass or weight of single particles. It was first suggested by Leslie and Hopkins about 100 years ago, and Wilfred Airy gave proof of it in 1885.‡ This conclusion is based

* *Minutes of Proceedings*, Inst. C. E., Vol. XCVIII, p. 93.

‡ *Minutes of Proceedings*, Inst. C. E., Vol. LXXXII, p. 25.

Mr. Bowlus.

on the fact that the impulse of a jet of water composed of equal parallel filaments varies as the square of the velocity and that the mass or weight varies as the cube of the diameter, making the weight vary as the sixth power of the velocity. As a matter of fact, on account of the greatly increasing velocity just above the bed of a stream, the particles are moved more easily because of a longer lever arm. Several experimenters have tried to verify this law or to find some other relation.

Dubuat* made some extensive experiments with a wooden trough in the Eighteenth Century, and Blackwell,† of England, made some about 1850. E. H. Hooker‡ has tabulated the results of many of these experiments. Hardly any of the experiments were made with materials resting on those of the same kind and shape. Gilbert, however, made some tests on this basis, and concluded that the diameter of particles transported varies with about the 2.7 power of the velocity, which conclusion is probably based on the mean diameter of the particles in a grade. It would have been more correct to use the diameter of the smallest particles, because those were the first to move, and platting the data on that basis the equation,

$$\text{Diameter} = 0.0032\ \text{Velocity},^{7.8}$$

is found to fit, approximately, indicating that the weight varies as the 7.8 power of the mean velocity.

The foregoing discussion refers, of course, to particles of the same material, specific gravity, and shape. With regard to shape, a round particle will be moved with less velocity than a square angular one. A cylindrical pencil will roll down a very gentle slope, a hexagonally shaped one requires a slope of from 5 to 10°, and one of square cross-section, from 20 to 30 degrees.

No attempt is made here to present the results of the present joint Government and State of California investigation of the Colorado River waters, which are somewhat comprehensive and are not yet fully worked up, but it is hoped that these results may be made available later. It has been the writer's intention merely to suggest the broad scope of this subject and to indicate its very important relation to the flood-control problem, also to call attention to a few of the common errors that are made in discussing the subject and to the confusion that exists with reference to the definition of the terms used.

Although the present investigations have been more or less confined to the Colorado River silt, it is hoped that they will be extended to include other streams of the Southwest, where the conditions are somewhat different.

Mr. Sonderegger.

A. L. SONDEREGGER,* M. AM. SOC. C. E. (by letter).—The discussions of Mr. Pohl and Mr. Wright have brought out interesting facts in regard to scouring in times of freshets.

Mr. Wright states that losses caused by erosion are "something which erosion has also built up again," and, furthermore, that the great quantities of material carried to the mouth come originally from the upper regions. This is, undoubtedly, true. Bank erosion which, at some points, appears to be enormous and contributes large quantities of silt, is only temporary, and eventually will be obliterated by the action of the river itself and the effect of drift carried by the winds. It also follows, logically, as he states, that on the Lower Mississippi, during past ages, alluvial action has exceeded the erosion. For these reasons, river control in the lower regions by means of levees is only a temporary expedient.

In Southern California, the débris at the mouth of canyons may contain blocks of 1 cu. yd. or more, interspersed with small boulders and coarse gravel. Invariably, it will be found that the blocks gradually disappear within a distance of 2 to 6 miles from the mouth of the canyon, below which point only coarse gravel and sand and some small boulders may be found.

Such steep, short débris cones indicate flashy peaks, with storms of brief duration, and, furthermore, that the quantity of coarse débris, transported in traction in each flood, is comparatively small and that the large blocks are not moved, except during such capital floods as occur only once in generations.

As regards the quantity of silt in suspension, the geological formation of the water-shed and the extent of the brush or timber cover will be of material influence. During the peak of 5 000 sec-ft., of March 2d, 1920, the San Gabriel River carried at Azusa, Cal., 55% of silt by weight, which percentage diminishes rapidly with a falling river. On April 19th, with a flow of 250 sec-ft., the water was clear.

Mr. Dunham has raised the question as to the methods used to determine the relative amount of seepage at higher and lower sections of the débris cone. It is physically impossible to gauge Southern California streams during flood times, at the apex of the débris cone, with a sufficient degree of accuracy to determine seepage losses occurring within a short distance. The beds are too irregular, and the velocities, as high as 30 ft. per sec., produce heavy wave action, so that cross-sections are difficult to determine, while the mass of floating débris makes it almost impossible to operate current meters.

The gaugings shown in Table 1 (page 1148), however, give an idea as to the amount of seepage in the San Gabriel River and other Southern California streams of moderate flow.

Paper No. 1450

EXPERIMENTS ON THE FLOW OF WATER THROUGH CONTRACTIONS IN AN OPEN CHANNEL

By E. W. Lane, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. William T. Lyle, D. C. Henny, Karl R. Kennison, R. D. Goodrich, and E. W. Lane.

Synopsis.

In the studies for the design of the flood prevention works of the Miami Conservancy District, the laws governing the flow of water through a contraction in an open channel assumed unusual importance. The available literature on the subject was uncertain and contradictory. To determine the true laws governing the phenomena, the writer carried on, during the summers of 1915 and 1916, a series of small-scale experiments. Although conditions growing out of the war prevented their completion, some interesting results were obtained, and it is believed that they throw considerable light on this little understood subject. The experiments consisted of measurements of flow through:

(*a*) A contraction with rounded edges, 1 ft. wide.
(*b*) A sharp edge contraction, 1 ft. wide.
(*c*) A sharp edge contraction, 2 ft. wide.
(*d*) A short flume with rounded entrance.
(*e*) A short flume with sharp corner entrance.
(*f*) An expanding or Venturi flume.

In the following paper a description of the apparatus and the method of making the experiments is given, together with the results.

Appendixes are attached containing:

I.—A brief description of the application of the theory of flow through contracted openings to the design of the flood prevention works of the Miami Conservancy District.

II.—A description of the unstable state of the stream below a sharp edge contraction.

Briefly stated, the most important conclusions drawn from these experiments are as follows:

The manner in which the flow of water through a contraction takes place, is entirely dependent on the conditions existing in that particular case. The two most common formulas are those of d'Aubuisson and Weisbach. Under certain conditions, one of these formulas may be applicable and, under another set of conditions, the other; while under still other conditions, neither should be used. The paper points out the various conditions of flow, the underlying causes, and the conditions under which they take place. The flow through a contraction is intimately connected with the phenomenon of "maximum flow", the theory of which is well known, but it is herein demonstrated experimentally, and its limitations are shown.

To explain the conditions of flow in the expanding flume, the theory of back-water curves was developed for a frictionless channel with a level bottom and variable width.

Certain forms of contractions were found to possess considerable merit as instruments for the measurement of flowing water.

The Theory of the Flow of Water Through a Contraction in an Open Channel.

The theory of the flow of water through a contraction in an open channel has been an unsettled problem in hydraulics for many years. At the time this investigation was undertaken, although available literature showed many discussions of the subject,* no record of experi-

ments could be found, which was sufficiently complete to establish any of the theories proposed. Since this study was undertaken, a valuable history and discussion of the various theories has been presented to the Society,* and, therefore, only a brief discussion of the theory will be given in this paper.

Although a number of hydraulicians have proposed formulas to represent the relation of the various factors entering into this problem, they are all based on one or the other of two theories. For convenience, these theories will be given the names of the men who probably first proposed them, that is, the d'Aubuisson and the Weisbach theories.

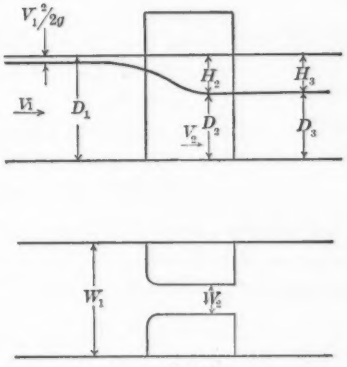

FIG. 1.

Symbols.—Fig. 1 represents the flow of water through a contraction, where:

V_1 = the mean velocity of the water above the contraction.

D_1 = the mean depth of the water above the contraction, including the velocity of the approach head. (The combining into one symbol of the observed depth above the contraction and the velocity of approach head, results in much simpler formulas, the meanings of which are more readily understood.)

W_1 = the mean width of the water above the contraction.

V_2 = the mean velocity of the water in the most contracted section of the channel.

D_2 = the mean depth of the water in the most contracted section of the channel.

W_2 = the mean width of the stream at the most contracted section of the channel.

H_2 = the drop of the water surface at the most contracted section, including the velocity of approach head.

* "Obstruction of Bridge Piers to the Flow of Water", by Floyd A. Nagler, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXII, p. 334 (1918).

g = the acceleration due to gravity.

$\frac{V_1^2}{2g}$ = the head due to the velocity of approach of the water above the contraction. This is usually included in D_1.

D_3 = the mean depth of the water in the channel below the contraction.

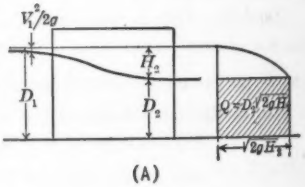
H_3 = the total drop of the water in passing through the contraction, or the observed drop plus the head due to the velocity of approach.

C = a coefficient to take account of losses due to friction, impact, etc. The subscripts, dA and W, designate the d'Aubuisson and the Weisbach coefficients, respectively.

Formulas.—According to the d'Aubuisson theory, V_2, the velocity in the contracted section, is equal to that produced by a drop, H_2, or V_2 is equal to $C_{dA}\sqrt{2\,g\,H_2}$, whence:

$$Q = W_2\,D_2\,V_2 = C_{dA}\,W_2\,D_2\sqrt{2\,g\,H_2} \quad \ldots\ldots\ldots\ldots (1)$$

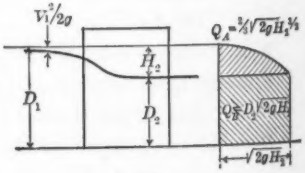
The d'Aubuisson formula is really only an application of the Bernouilli theorem. The discharge according to this formula is represented graphically, for a unit width of channel, by the cross-hatched portion of Fig. 2 (*A*).



(A)

Weisbach considered the flow as being made up of two parts: (*a*) a part equal to that which would flow over a weir with a crest length of W_2 and a head on the crest of H_2, or,

$$Q_A = C_A\,W_2\,\frac{2}{3}\sqrt{2\,g}\,H_2^{\frac{3}{2}} \ldots (2)$$



(B)

FIG. 2.

and (*b*), a part equal to that which would flow through an orifice of width, W_2, and height, D_2, under a head of H_2, or

$$Q_B = C_B\,W_2\,D_2\sqrt{2\,g\,H_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

These two portions are represented graphically, for a unit width, by

the two cross-hatched portions of Fig. 2 (*B*). In the formula, the two parts are combined with a single coefficient, giving:

$$Q = C_W W_2 \sqrt{2g} \left(\frac{2}{3} H_2^{\frac{3}{2}} + D_2 H_2^{\frac{1}{2}} \right) \ldots\ldots\ldots\ldots (4)$$

It will be noted that Part (*b*) of the discharge, according to the Weisbach theory, is exactly equal to the total discharge according to the d'Aubuisson theory. The Weisbach theory, therefore, always gives a theoretical discharge greater by the amount of the first part, $W_2 \frac{2}{3} \sqrt{2g}\, H_2^{\frac{3}{2}}$. In determining the value of the coefficient experimentally, where Q, W_2, D_2, and H_2, are measured, the coefficient, C_W, in the Weisbach formula, for a given experiment, will always be lower than the coefficient, C_{dA}, of the d'Aubuisson theory.

It is usually impractical to determine the depth, D_2, of the water in the most contracted section, on account of the difficulty of measuring the height of the water surface at this point. A common practice is to measure the water surface elevation below the contraction, and assume that the surface in the most contracted section is at the same elevation. For instance, in computing the height of back-water at a bridge opening, the usual practice is to assume that the water surface elevation in the most contracted section is the same as that in the river channel immediately below the bridge. In most cases of bridge openings, this is very nearly the true condition. For some contractions, however, the assumption is far from the truth, and it has a very important effect on the nature of the coefficient which must be used to obtain the true values of discharge. In the computations of the three experimental contractions, this assumption was made, and its effect will be discussed in connection with the results of these experiments.

Description of Experimental Plant.

The experiments made by the writer to study the flow of water through contracted openings, were carried on in a rectangular channel, approximately 6.8 ft. wide and 2 ft. deep. The sides were formed by sheeting which had been used in connection with the laying of a water main, and the bottom was of gravel and silt. The channel paralleled the Mad River and received its water supply from it. The head necessary for the experiments was created by a fall of 2 ft. between the upper end of the channel and the point at which the water discharged back

into the river. Of this drop, about 1½ ft. was available for experimental purposes.

The quantity of water used in the experiments was controlled by a by-pass in the side of the channel, about 40 ft. from its upper end. This consisted of a rectangular opening through which the excess flow was discharged back into the river, the quantity being regulated by small stop-logs. Forty feet below the regulator was the weir for measuring the discharge through the experimental contractions, which were built in the channel 86 ft. farther down stream.

Measuring Weir and Float Gauges.—The measuring weir was of the Cippoletti type, with a crest length of 2 ft. The dimensions of its setting were made as nearly as possible like those of the weir on which experiments* were made by Messrs. W. G. Steward and J. S. Longwell, Jun. Am. Soc. C. E., in order that the coefficients derived by them might be used in computing the discharge. The weir bulkhead was of wood, while the crest was formed of heavy galvanized iron, cut to a straight, smooth edge. The weir was in place several months, and the swelling of the wood and consequent change of crest elevation was complete, before any discharge measurements were made. As in the setting used by Messrs. Steward and Longwell, the crest of the weir was 1 ft. above the bottom of the channel of approach, and the head was measured at a point 10 ft. up stream from the bulkhead.

Float gauges of unusual design were used to measure the head. (Plate XVIII.) They were set in a wooden pit, 6 by 6¾ in., set outside the channel and connected to it through the sheeting by a piece of ¾-in. pipe, 3 in. long, ending flush with the side of the channel. In order that no cross-currents might be created near the end of the pipe by the irregularities of the sheeting, a piece of galvanized iron was placed over the side of the channel at this point, with a hole drilled through it where it covered the end of the pipe. Inside, and resting on the bottom of the pit, was a cylindrical tube of galvanized iron, 5 in. in diameter, open at the top. In the sides of this cylinder, 1 in. above the bottom, were four holes, ⅜ in. in diameter, spaced equally around the circumference. This tube served as a guide for the float, which was cylindrical in shape, 4 in. in diameter and 2 in. high, with a conical bottom, to prevent air being entrapped beneath it thus alter-

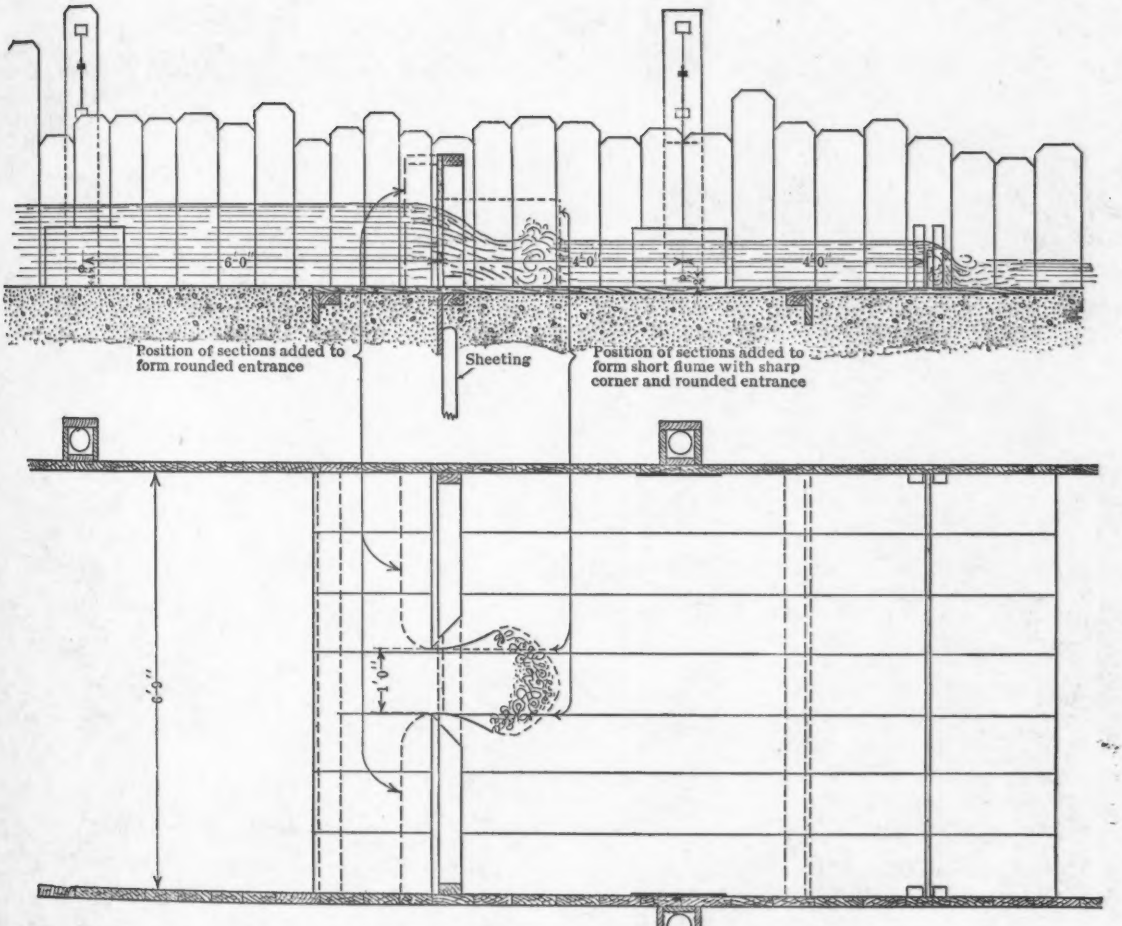
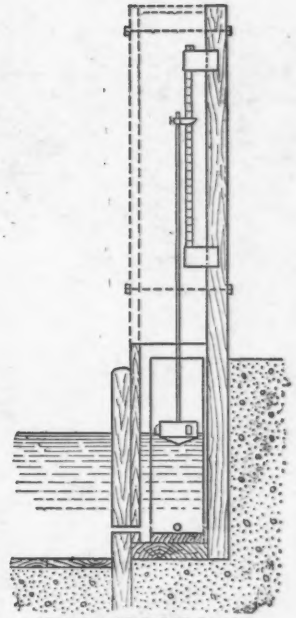
LANE ON
FLOW OF WATER THROUGH CONTRACTIONS.



HORIZONTAL AND VERTICAL SECTIONS OF SHARP EDGE CONTRACTION



SECTION OF FLOAT GAUGE.

ing its buoyancy. On the sides of the float were three fins, ½ in. wide, extending out radially to prevent it from rubbing on the side of the tube. Connected to the float by a small brass rod, was a pointer which moved over a steel tape graduated to hundredths of a foot, the tape serving the double purpose of a scale for reading the position of the float and as a guide for the pointer. The gauges were fitted with a wooden box-like cover which was bolted and locked on them when not in use, to prevent their being tampered with. When the experiments were undertaken, it was proposed to place the cylinder and float directly in the channel. This was found to be impracticable, on account of cross-currents, and they were enclosed, therefore, in boxes and placed outside the channel, connected to it with pipes as described.

Float gauges of a somewhat similar pattern, in which the float moves in a cylinder which is connected at the bottom directly to the side of the channel, have been used for several years in the Hydraulic Laboratory of Cornell University, and have been found to be very satisfactory devices for measuring head, particularly if there is considerable wave action. The float gauge has several advantages over the hook gauge for reading water levels. Readings may be taken more rapidly with it; and instantaneous readings, maximum and minimum, and the character of surges can be readily observed. The writer believes that the accuracy obtainable under ordinary conditions is equal to, and, in disturbed water, exceeds that which it is possible to obtain with a hook gauge.

Contractions.—A section of the sharp edge contraction is shown on Plate XVIII, and Fig. 3 shows the flow of water through it. The contraction consisted of two vertical walls, ending with sharp vertical edges formed of galvanized iron, extending out at right angles from the sides of a rectangular channel. The bottom of the channel at this point was formed of planed boards, with cut-off walls below to prevent seepage under the contraction. The height of the water surface above the contraction was measured by one float gauge, 6 ft. above the most contracted section, and the down-stream height by two gauges, one on each side of the flume, 4 ft. below this point. The height of the water surface below the contraction was controlled by a series of small stop-logs, 4 ft. below the down-stream gauges. It was first planned to place this regulator at a considerable distance below the contraction, but when so placed an unstable condition of the jet resulted, which neces-

sitated placing the stop-logs near the contraction. This condition of the jet is described in full in Appendix II. The curved contraction was formed by placing attachments of galvanized iron, curved to a radius of 0.5 ft. above the sharp edge contraction, as shown on Plate XVIII and Fig. 4.

Short Flumes.—The short flume with sharp corner entrance was formed by placing two galvanized iron sheets, 2 ft. long, below the sharp edge contraction, as shown on Plate XVIII. These sheets were fastened securely to the bottom of the channel and braced at the top to hold them in position. The short flume with rounded entrance was formed by placing these pieces below the contraction with rounded entrance.

Expanding Flume.—Plate XXIV shows the cross-section of the expanding or Venturi flume. This flume had sheet-iron sides, tacked to a wooden form which was cut accurately to the desired shape. The entrance was formed by curves of 0.5 ft. radius. Below these, the sides were parallel, 1.0 ft. apart, for 2.0 ft., at which point they began to diverge along the parabolic curve, $y = 0.0178\ x^2$, reaching a distance of 3.0 ft. apart at the lower end of the flume, the total length being 10.0 ft. The flume was set in the channel and connected at the upper end with the same bulkhead that was used for the sharp edge contraction. The bottom of the flume was not exactly level, the down-stream end being slightly higher than the up-stream end. Practically all the slope was in the expanding section of the flume and probably had little, if any, effect on the results.

Point Gauge.—For the determination of the elevation of the water surface in the short and expanding flumes, a point gauge was used. The rod was graduated to hundredths of a foot and moved vertically past a vernier, from which the thousandths of a foot could be read. The rod and vernier were conveyed on a carriage which moved across the channel on a beam, at the ends of which were bearing plates clamped to the framing of the sides of the flume. The position occupied by the bearing plates at each measuring section was marked on the framing of the flume, in order that the beam could be placed in exactly the same position for each reading at that section.

Experimental Methods.

Weir and Float Gauges.—Two methods of determining the gauge zero of the weir were used. In the first of these, readings were taken

FIG. 3.—ONE-FOOT SHARP EDGE CONTRACTION, SHOWING FLOAT GAUGES.

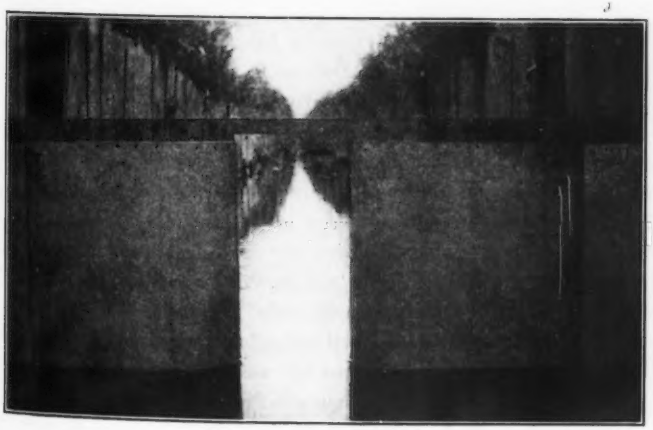


FIG. 4.—CONTRACTION WITH ROUNDED EDGES, UP-STREAM SIDE.

with an engineer's level and rod at several points on the crest of the weir, and on the point of a stationary hook which was fastened to the side of the channel near the float gauge. This hook had a sharp point like an ordinary hook gauge, but was constructed of much heavier material, in order to carry the weight of the level rod without deflection. The lower end of the channel was closed, and water was admitted very slowly until the surface rose slightly above the point of the hook. At the instant the surface reached the point of the hook, a reading of the float gauge was taken. Water was then discharged slowly until the surface again fell below the point, another reading of the float gauge being taken at the instant the water surface reached the point of the stationary hook. The mean of several such observations, which never varied more than a few thousandths of a foot, was taken as the reading of the float gauge corresponding to the elevation of the point of the hook. Knowing the difference in elevation between the crest of the weir and the point of the hook, as determined by level-rod readings, the reading of the float gauge corresponding to the elevation of the weir crest could be readily determined.

The second method of determining the weir gauge zero was by means of the point gauge. Water was ponded in the experimental channel to a sufficient depth to cover the weir crest. The difference in elevation between the crest of the weir and the water surface in the channel was measured with the point gauge at several points along the weir crest, readings of the float gauge being noted at the same time. From these, the float-gauge reading corresponding to the elevation of the weir crest was determined. Both these methods were also used in determining the gauge reading equivalent to the bottom of the contractions.

Contractions.—For the experiments on the contractions with sharp edges, and on the contraction with the rounded entrance, the procedure was the same. Each run consisted of five observations of head on the measuring weir, five on the gauge above the contraction, and ten on each of the gauges below the contraction. The readings on the weir and up-stream gauge varied little during a run, but as a result of the turbulent water below the contraction, considerable fluctuation occurred in the down-stream gauge readings, and, therefore, more observations were required to arrive at an accurate mean. The time required for a run was about 30 min.

Short and Expanding Flumes.—The width of the short and expanding flumes was measured at several elevations at each observation section, by large inside calipers. From these measurements a table was prepared, showing the area of the cross-section of the flume at each observation section for the various depths. To refer the observations on the water surface with the point gauge, the readings of the float gauges, and the elevation of the bottom of the flume at each station, to a common datum, the procedure was as follows: Water was ponded in the flume, the beam of the point gauge was clamped in the proper position, and readings were taken on the water surface and bottom of the flume, at each measuring station, at the same points in the cross-section, which were used later in the flow observations. Simultaneous observations of the water surface elevation, as recorded by the float gauges, were also made. The difference, at any measuring station, between the mean of the readings on the water surface and the mean of those on the bottom, gave the mean depth of water at that section. Knowing the float-gauge readings, as observed for this water surface elevation, the gauge reading corresponding to the bottom of the flume was readily computed. In like manner, the reading of the float gauge equivalent to the mean height of the point-gauge beam was determined for each measuring station.

A run consisted of observations of discharge, depth above and below the contraction, and water surface elevation at the various observing stations. Readings of the weir gauge and the gauges above and below the flumes, for determining the values of the discharge, Q, and of the depths, D_1 and D_3, were made after the measurement of the elevation of the water surface at each station. These stations were spaced along the flume at such distances apart that the profile of the mean water surface could be determined accurately. This was approximately 0.25 ft. in the narrow section of the flumes, but farther apart in the wider portions. At each measuring section in the narrower portions, readings of the water surface elevation were taken at each side and at every 0.2-ft. point between, although, in some cases, they were taken every 0.1 ft. In the lower 2½ ft. of the expanding flume, readings were usually taken 0.3 ft. apart.

Computations.

In the computations for these experiments, all distances were taken to the nearest thousandth of a foot, discharge to the nearest thousandth

of a cubic foot per second, and the coefficients were computed to three decimal places. The multiplications were performed with a Thacher slide-rule or a five-place logarithmic table.

Weir.—The discharge over the weir was computed by the formula:

$$Q = C\,L\left(H + \frac{V^2}{2\,g}\right)^{\frac{3}{2}} \qquad (5)$$

The values of C were taken from a curve showing the relation of the head to the value of the coefficient, as obtained from the experiments of Messrs. Steward and Longwell previously referred to, on a 2-ft. Cippoletti weir. The length of the crest, L, was obtained by accurate measurements, and H was determined by subtracting the gauge reading corresponding to the weir crest elevation from the reading of the water surface above the weir, corrected for velocity of approach. On all experiments except those on the expanding flume, the mean of the weir gauge readings was used in computing the discharge. For the expanding flume experiments, the discharge corresponding to each gauge reading was computed. The values of the velocity of the approach head, $\frac{V^2}{2\,g}$, were read from a curve computed to show its magnitude for the various values of H.

Contractions.—For the contractions, the equation for the computation of the coefficients in the d'Aubuisson formula was:

$$C_{dA} = \frac{Q}{W_2\,D_2\sqrt{2\,g\,(D_1 - D_2)}} \qquad (6)$$

The quantity, D_1, the total depth above the contraction, was determined from the mean of the up-stream gauge readings, by subtracting from this mean the reading of the gauge corresponding to the elevation of the bottom of the contraction. To this was added the velocity of approach, $\frac{V_1^2}{2\,g}$, V_1 being computed by dividing the measured discharge by the area of the approach channel at the depth, D_1. The value of the width of the contraction, W_2, was determined by measurement with a scale or caliper. The depth at the most contracted section, D_2, was not measured, but, as has been previously noted, the values of D_3, the depth below the contraction, which were determined from the readings of the down-stream gauges, were used in place of D_2, in computing the coefficients by the various formulas.

The computation of the coefficient by the Weisbach formula:

$$C_W = \frac{Q}{W_2 \sqrt{2g} \left(\frac{2}{3} H_2^{\frac{3}{2}} + D_2 H_2^{\frac{1}{2}} \right)} \quad \ldots\ldots\ldots\ldots (7)$$

was made in a manner similar to that for the d'Aubuisson formula. As the bottom was level, $H_3 = D_1 - D_3$, the measured values of H_3 and D_3 being used in the computations, in place of H_2 and D_2, respectively.

Short Flumes.—The computations of the results of the experiments on the short flumes were made in a manner similar to those for the contractions. The same formulas were used, but the coefficients were worked out for each measuring station along the length of the flume, the value of D_2 being the mean depth, and that of W_2 the mean width, as measured for that station. The discharge throughout the run was practically constant, and the mean discharge, therefore, was used for Q. As the bottom was level, $H_2 = D_1 - D_2$. In computing the coefficients for the points below the end of the short flume, the width, W_2, was assumed to be the same as that of the flume at its lower end. It will be noticed that this is the same, in effect, as the assumption usually made in computing the discharge at bridge openings, and, under certain conditions, may lead to erroneous results, as shown on page 1186.

Expanding Flume.—In the experiments on the expanding flume, the coefficients were worked out for each observation section. During a run, a slight change of discharge took place and, therefore, the discharge at the time the measurement was made at any station was used in the computations for that station. The formulas used for the contractions had to be modified somewhat for the expanding flume, as the bottom was not exactly level and $D_1 - D_2$ was not equal to H_2. The true drop was determined by subtracting the elevation of the water surface in the flume, as determined by the point gauge, from the elevation of the water surface above the contraction, as determined by the float gauge, the latter elevation being corrected for the velocity of approach. The measured depth and width at each station were used for D_2 and W_2, respectively.

Results of Experiments on Contractions.

The results of these experiments are given in numerical form in Tables 1 to 10, inclusive. They are also shown graphically on many

of the diagrams. The consistency of the results is highly satisfactory, considering the conditions. In these experiments, it was necessary to measure the difference in elevation between two water surfaces, one of which was subject to considerable fluctuation. In addition, this difference of water level was small, averaging not more than 0.4 ft. A slight error in the observation of either of the water levels, therefore, would result in a considerable error in the coefficient.

Contraction with Rounded Edges.—The results of the experiments on the contraction with rounded edges, on the basis of the d'Aubuisson and the Weisbach formulas, are given in Table 1, and are shown graphically on Figs. 5 and 6. Each run is plotted, its position showing the relation of D_1, the depth above the contraction, to D_3, the depth below. At each of these points is recorded the values of the coefficient obtained for that run. Lines of equal drop (H_3), are drawn for each 0.1 ft., as well as lines of equal values of the ratio, $\frac{H_3}{D_3}$, for each 0.1.

It will be noticed that the coefficients for this contraction, according to the Weisbach formula, vary from 0.693 to 0.815, while those of the d'Aubuisson formula vary from 0.846 to 1.074. It would seem that neither formula is a rational expression for the true condition of flow, since with the rounded edges there would be no contraction of the jet, and from the coefficient for orifices with rounded edges, one would expect that the coefficient in the true formula for this contraction would be nearly unity. The d'Aubuisson coefficients fit this condition more closely than those of the Weisbach formula. Some of the d'Aubuisson coefficients, however, have values greater than unity,

which, as there must be some loss due to friction, would seem to prove that this formula is irrational. A closer study, however, in connection with the conditions of flow existing in those runs which gave coefficients greater than unity, shows that because of the assumptions made in computing the coefficients, these results would be expected.

Instead of proving the irrationality of the d'Aubuisson formula, they really tend to substantiate it.

Consider the d'Aubuisson formula:

$$Q = C_{dA}\, W_2\, D_2 \sqrt{2\, g\, H_2}$$

$$= C_{dA}\, W_2\, D_2 \sqrt{2\, g\, (D_1 - D_2)} \qquad (8)$$

Differentiating with respect to D_2 and equating dQ to zero, in order

to find the value of D_2 which gives the maximum discharge, it is found that this occurs when D_2 is equal to $\frac{2}{3} D_1$, or when H_2 is equal to $\frac{1}{2} D_2$, or $\frac{1}{3} D_1$. The maximum discharge, therefore, is:

$$Q = C_{dA} W_2 \frac{2}{3} D_1 \sqrt{2 g \frac{D_1}{3}} \quad \ldots\ldots\ldots\ldots\ldots (9)$$

$$= C_{dA} W_2 3.09 D_1^{\frac{3}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

In flowing, on a level bottom, from a body of water at one elevation to another at a lower elevation, where D_3 is less than $\frac{2}{3} D_1$, the water tends to assume the condition of maximum discharge, and flow in the same manner as if D_3 were equal to $\frac{2}{3} D_1$. This phenomenon was pointed out by Unwin* and Frizell† and has been described before the Society.‡

From Fig. 5, it will be seen that all those runs which give d'Aubuisson coefficients greater than unity, have $\frac{H_3}{D_3}$ greater than 0.5. This is also shown on Fig. 7, where the d'Aubuisson coefficients are plotted against the ratio, $\frac{H_3}{D_3}$. The flow in these cases, therefore, was similar to the condition of maximum discharge and had a depth in the most contracted section of, approximately, $\frac{2}{3} D_1$. The theoretical discharge according to the d'Aubuisson formula was computed on the assumption that the depth of the stream in the most contracted section was equal to D_3, the depth in the pool below the contraction. For those runs in which D_3 was less than $\frac{2}{3} D_1$, D_3 was less than D_2, and the computed discharge, therefore, was less than the actual discharge, causing coefficients greater than unity. For this reason, the d'Aubuisson formula should not be used where $D_3 < \frac{2}{3} D_1$, unless the value of D_2 is actually measured and used in the computations.

* *Encyclopedia Britannica*, under "Hydrodynamics".
† "Water Power", by Frizell, pp. 198-200.
‡ *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 338.

If one computes a coefficient, C_M, showing the ratio of the actual discharge to the "maximum" discharge, $Q = 3.09\ W_2\ D_1^{\frac{3}{2}}$, for those runs in which H_3 is greater than $\frac{1}{2}\ D_3$, it will be found that, in some cases, C_M is greater than unity, or that the actual discharge was greater

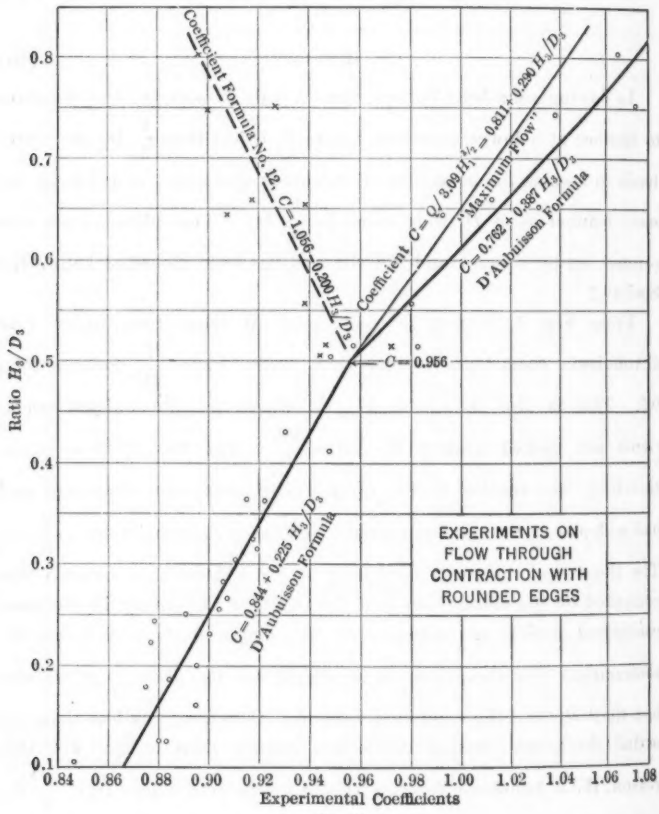

FIG. 7.

than the maximum possible, according to this theory. Here, again, an examination of the condition of flow shows the reason for this discrepancy. The conditions which give rise to the "maximum flow" are shown on Fig. 8, the cross-hatched area representing graphically

the discharge per unit width. In this case, $D_2 = D_3 = \frac{2}{3} D_1$. In those cases where the coefficient, C_M, is greater than unity, D_3 is less than $\frac{2}{3} D_1$, and the conditions of flow are as shown on Fig. 9.

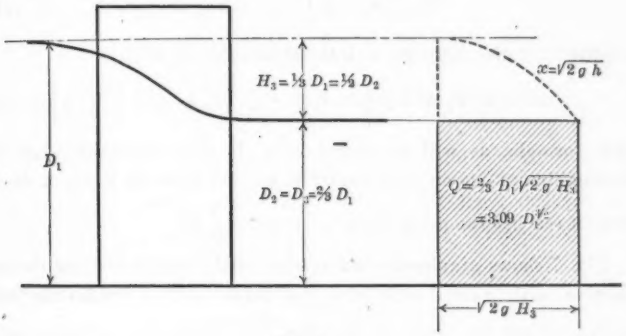

FIG. 8.

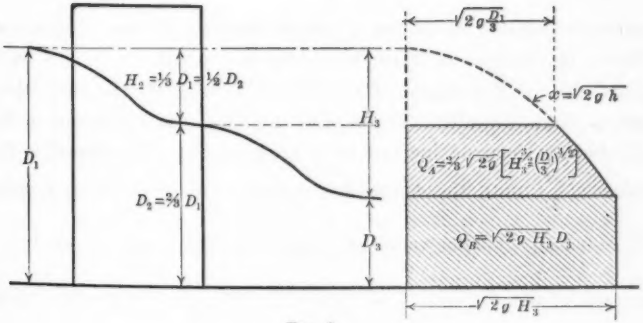

FIG. 9.

Under these conditions, all those particles of water which flow through the contraction below the elevation of the down-stream water surface, have a velocity due to the difference of elevation of the water surface above and below the contraction, or $\sqrt{2 g H_3}$. They make up the lower cross-hatched rectangle of Fig. 9, with an area of $D_3 \sqrt{2 g H_3}$. Those particles which pass out of the contraction at an elevation above

the lower pool, have a velocity, depending on their elevation, varying from $\sqrt{2\,g\,\frac{D_1}{3}}$ to $\sqrt{2\,g\,H_3}$, the total discharge through this section being

$$W_2\,\frac{2}{3}\,\sqrt{2\,g}\,\left[H_3^{\frac{3}{2}} - \left(\frac{D_1}{3}\right)^{\frac{3}{2}}\right] \ldots\ldots\ldots\ldots (11)$$

and the total discharge through the contraction being

$$Q = C\,W_2\,\sqrt{2\,g}\left[D_3\,H_3^{\frac{1}{2}} + \frac{2}{3}\left(H_3^{\frac{3}{2}} - \left\{\frac{D_1}{3}\right\}^{\frac{3}{2}}\right)\right] \ldots . (12)$$

This formula, as will be shown later, is only applicable where the flowing stream has an opportunity to expand laterally when, or shortly after, it reaches the point where its depth is $\frac{2}{3}\,D_1$.

Fig. 7 shows graphically the results of the experiments on the contraction with curved entrance, the values of the coefficients being plotted against the values of the ratio, $\frac{H_3}{D_3}$. It will be seen that the values of the coefficient seem to be dependent on this ratio, that is, all cases having the same value of $\frac{H_3}{D_3}$ have the same coefficient. This fact makes it possible to obtain a simple formula for the coefficient of these experiments, as it combines the two variables, D_1, the depth above, through the relation $D_1 = H_3 + D_3$, with D_3, the depth below, into a single variable. The results show that the coefficients in the d'Aubuisson formula increase at a uniform rate, with respect to the values of $\frac{H_3}{D_3}$, until the depth of maximum flow is reached, or where $H_3 = 0.5\,D_3$. For the values of $\frac{H_3}{D_3}$ up to 0.5, the coefficient can be expressed by the formula, $C = 0.844 + 0.225\,\frac{H_3}{D_3}$. Above this critical depth, the coefficient increases at a rapid rate, soon becoming greater than unity, for the reason already explained. This portion also seems to follow a straight line law, with a formula, $C = 0.762 + 0.387\,\frac{H_3}{D_3}$. If the formula, $Q = C_M\ 3.09\ W_2\ D_1^{\frac{3}{2}}$, is used for the discharge, where $\frac{H_3}{D_3} > 0.5$, the coefficients follow a line as shown, which differs little from that of the d'Aubuisson formula. This coefficient also

becomes greater than unity, as previously explained. The experimental points were not put on the diagram, in order to avoid confusion, as many of them fall close to those of the d'Aubuisson formula. This curve has a formula, $C = 0.811 + 0.290 \frac{H_3}{D_3}$. The coefficients determined by Formula (12), for runs where $\frac{H_3}{D_3} > 0.5$, also seem to follow a straight line, decreasing uniformly as the ratio, $\frac{H_3}{D_3}$, increases, according to the equation, $C = 1.056 - 0.200 \frac{H_3}{D_3}$. Algebraically, if the formula for C_{dA} follows a straight line, those for C_M and the coefficient for Formula (12) do not necessarily follow straight lines. Practically, however, the straight line relation seems to fit all three cases.

From the results of the experiments on the short flume with rounded entrance and on the expanding flume, it seems probable that the difference between the theoretical and actual discharge of the contraction with rounded edges is due to a loss of the nature of an impact rather than a friction loss. The increase of the coefficient, C_{dA}, as the value of $\frac{H_3}{D_3}$ increases, shows that this loss becomes a relatively smaller portion of the head, as the value of $\frac{H_3}{D_3}$ increases. The variability of the coefficient may be in part due to a slight recovery of the elevation head of the water after passing through the contraction. Such a recovery occurred in the short flume with rounded entrance, as will be explained later, but the measurements on the contraction with rounded edges were not of such a nature that its presence, if it existed, could be shown. The phenomenon of change from stream line to turbulent flow may also be a contributing factor. It has been suggested that this change of state of motion of the water is responsible for certain phenomena of flow over a sharp crested weir at low heads.*

The decrease in the coefficient for Formula (12), where $\frac{H_3}{D_3} > 0.5$, may be due to an assumption on which the formula is based, which may be only approximately true, namely, that when $\frac{H_3}{D_3} > 0.5$, H_2, the water

* "Control of Water", by Parker, p. 22.

surface drop, in flowing through the contraction, is always equal to $\frac{1}{3} D_1$. This is probably true when $D_3 = \frac{2}{3} D_1$, but a somewhat different set of conditions exist when $D_3 < \frac{2}{3} D_1$, which may cause the drop of the water surface to follow a slightly different law. Just what this law is would probably have to be determined by measurement. H_2 would probably not be a constant proportion of D_1, but would probably start at $\frac{1}{3} D_1$, when $\frac{H_3}{D_3} = 0.5$ and, as the decreasing coefficients seem to indicate, become a larger part of D_1 as the ratio, $\frac{H_3}{D_3}$, increases.

Sharp Edge Contractions.—The results of the experiments on the sharp edge contractions are given in Tables 2 and 3. It will be noticed that for both the 1 and 2-ft. widths, the values of the coefficients are practically constant for the Weisbach formula, while for the d'Aubuisson formula, they vary over quite a range. Moreover, the value of the coefficient in the Weisbach formula is in fair agreement with the values found on the sharp edge weir and orifice. If the conditions of flow at these contractions are examined, it is evident that, for this case, the Weisbach, rather than the d'Aubuisson, formula is the rational one. The reason for this is evident from a study of Fig. 2. In the case of the contraction with rounded edges, where $H_3 < \frac{1}{2} D_3$, all the drop takes place within the contraction. Each particle of water, therefore, acquires a velocity depending on the difference of the water level above and below the contraction, or $\sqrt{2 g H_3}$, and the total discharge is, therefore, $Q = W_2 D_3 \sqrt{2 g H_3}$. In the sharp edge contraction, however, the greater part of the drop takes place after the water has passed through the contraction. (Fig. 3.) Each particle above the tail-water level, as it passes through the contraction, has a velocity in proportion to its drop, or to $\sqrt{2 g h}$, and the discharge per unit width of this portion is:

$$\int_0^{H_3} \sqrt{2 g h} = \frac{2}{3} \sqrt{2 g} H_3^{\frac{3}{2}}.$$

All the particles below the tail-water level have the same velocity, or $\sqrt{2 g H_3}$, and the discharge per unit width of this portion is

$D_3 \sqrt{2\,g\,H_3}$. Combining these two parts, we have the Weisbach formula:

$$Q = C_W\, W_2 \sqrt{2\,g} \left(\frac{2}{3} H_3^{\frac{3}{2}} + D_3\, H_3^{\frac{1}{2}} \right).$$

As H_3 and D_3 were actually measured and used in the computations of the results of the sharp edge contractions, it will be seen that if H_3 and D_3 are used in place of H_2 and D_2, the flow through the sharp edge contraction agrees with the Weisbach theory. The Weisbach formula is essentially the same as the theoretical formula for a submerged weir, and the condition of flow through a sharp edge contraction is similar to that which theoretically takes place over such a weir. In all cases of flow through contractions, the individual water particles follow the Bernouilli theorem, and if the area of the stream from the sharp edge contraction was measured where it reaches the elevation of the down-stream pool, the discharge no doubt would be found to be $Q = A \sqrt{2\,g\,H_3}$, where A represents this area.

The Weisbach coefficients for the sharp edge contractions are not exactly constant, but vary slightly, being larger for the smaller values of $\frac{H_3}{D_3}$. This might indicate that the coefficients for the two portions (Formulas (2) and (3)) have different values, instead of the same value, which is an assumption of the Weisbach formula. The formula on this basis, therefore, would be :

$$Q = W_2 \sqrt{2\,g} \left[C_A \frac{2}{3} H_3^{\frac{3}{2}} + C_B\, D_3\, H_3^{\frac{1}{2}} \right] \ldots\ldots\ldots (14)$$

The coefficients in this formula may be readily found by transferring Formula (14) into

$$Q = \left(\frac{2}{3}\, C_A \frac{H_3}{D_3} + C_B \right) W_2 \sqrt{2\,g}\, D_3\, H_3^{\frac{1}{2}} \ldots\ldots\ldots (15)$$

It will be recognized that this has the same form as the d'Aubuisson formula, except in this case the coefficient is a variable composed of two parts, one of which is a constant, while the other is a linear function of $\frac{H_3}{D_3}$. If, therefore, the d'Aubuisson coefficients of these experiments are plotted against their respective values of $\frac{H_3}{D_3}$ (Fig. 10), and the straight line most nearly representing the points is drawn, we have directly the

values of C_B and C_A, C_B being the value of the d'Aubuisson coefficient, as shown by this line, when $\frac{H_3}{D_3} = 0$, and C_A being $\frac{3}{2}$ of the slope of the line with respect to the axis along which the values of the ratio, $\frac{H_3}{D_3}$, were plotted.

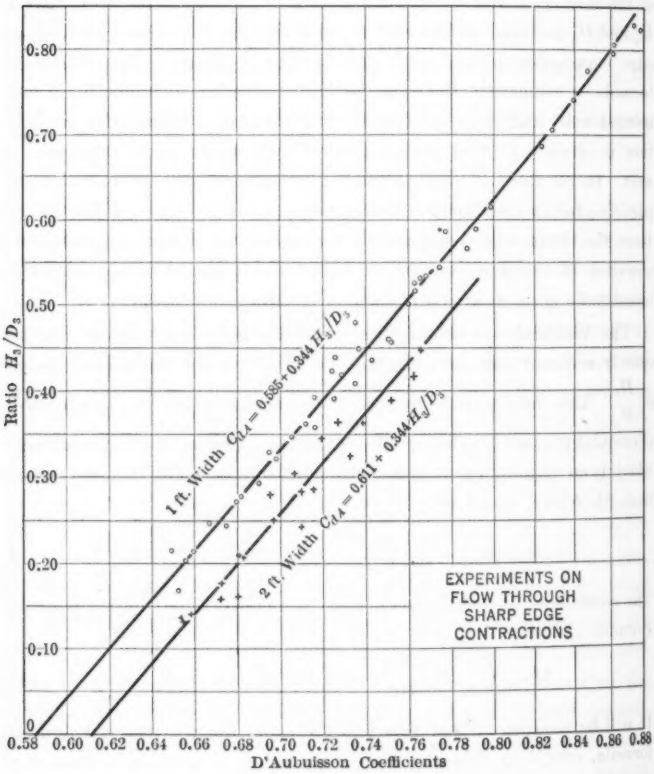

FIG. 10.

Fig. 10 shows the results of this plotting for both the 1-ft. and 2-ft. widths, and the d'Aubuisson forms thus derived for the discharges are:

$$Q = \left[0.585 + 0.344 \frac{H_3}{D_3}\right] W_2 \sqrt{2g}\, D_3\, H_3^{\frac{1}{2}} \quad \ldots\ldots\ldots (16)$$

for the 1-ft. width, and

$$Q = \left[0.611 + 0.344 \frac{H_3}{D_3}\right] W_2 \sqrt{2\,g}\, D_3\, H_3^{\frac{1}{2}} \ldots\ldots\ldots (17)$$

From these, the coefficients in Formula (14) are, therefore, for the 1-ft. width, $C_B = 0.585$, and $C_A = \frac{3}{2} \times 0.344 = 0.516$, and for the 2-ft. width, $C_B = 0.611$ and C_A also $= 0.516$.

It will be noticed that the coefficient for that part of the flow below the tail-water elevation is larger than that for the part above. The reason for this is probably because the portion below is contracted on two sides only, while that above is contracted on both sides and top, since the upper surface, as it flows through the contraction, has already dropped a certain distance and does not remain at the elevation of the head-water, as assumed in the Weisbach formula. This tends to cause a greater contraction in the upper part of the stream and, therefore, produces a lower coefficient for this part.

The coefficient, C_A, for both widths is found to be the same, but as the range covered by the experiments on the 2-ft. width was small, due to the limitations of the apparatus, the values are not clearly defined, and experiments covering a larger range might show them to differ slightly. The writer believes that the same coefficient in the two cases is the result of a balance of the effects of the contraction on the sides and upper surface of this part of the flow. The effect of the contractions on the sides is less for the larger width, as is shown by the greater coefficient for that width, for the portion of the stream below the tail-water level. On this part only the side contractions are acting. The contraction due to the drop of the water surface before passing between the sharp edges is probably less for the narrow width, since the contraction of the stream at the sides tends to prevent this surface drop from taking place. The effect of these side contractions is greater on the narrower width, since, in this case, they occupy a greater proportion of the width of the opening. The tendency of the contraction on the sides of the 1-ft. width to be larger, and on the top to be smaller, than for the 2-ft. width, probably equalize each other, and give the same coefficients on both widths.

The flow in the section of the contraction above the tail-water level is probably somewhat similar to that through a rectangular weir with

end contractions. The late James B. Francis, Past-President, Am. Soc. C. E., found that the effect of the end contractions was to reduce the effective length of the weir by 0.2 H. His formula, however, if carried to extremes, leads to a negative discharge, and experiments* show that although it is applicable up to a certain point, for widths narrower than this, the end contractions interfere in the center, and the reduction of the effective length becomes less than 0.2 H. The discharge, therefore, tends to become more like that through an orifice. As it seems reasonable that, for a very large width, the discharge of a sharp edge contraction would be practically the same as for one with rounded edges, one would expect that, as the width of the contraction was increased, the coefficient, C_B, would increase, while C_A would decrease.

Different coefficients for the parts of the flow above and below the tail-water level have been found for the flow over a submerged weir. Mr. Francis† found the coefficients for a submerged weir without end contractions to be 0.622 and 0.573 for the part above and below the tail-water, respectively. For the part above, the coefficient for the weir is larger than that of the contraction. This is probably due to the fact that, in the case of the weir, the coefficient expresses the effect of the surface drop only, while, in the case of the contraction, it is due to both the surface drop and the effect of the sides. On the other hand, for the part below the tail-water level, the coefficient for the weir is slightly smaller than for the contractions, indicating that the effect of the sides of the contraction is less than that of the crest of the weir.

General Formula for Contractions.

A general formula for contractions may be developed in a manner similar to Formula (12), by using the water surface drop, H_2, instead of $\frac{1}{3} D_1$. This formula is

$$Q = C_G \; W_2 \sqrt{2g} \left[D_3 \, H_3^{\frac{1}{2}} + \frac{2}{3} \left(H_3^{\frac{3}{2}} - H_2^{\frac{3}{2}} \right) \right] \ldots\ldots (18)$$

When the conditions are such that all the drop takes place after the water passes through the contraction, H_2 is zero, and the formula

* *Cornell Civil Engineer*, April, 1912.
† *Transactions*, Am. Soc. C. E., Vol. XIII (1884), p. 303.

becomes the same as that used in computing the Weisbach coefficients. When the drop takes place within the contraction, H_2 is equal to H_3, and the formula becomes that used in the computation of the d'Aubuisson coefficients. In order for this formula to apply, it is necessary for the flowing stream to be able to expand laterally without hindrance immediately after passing through the narrowest portion of the contraction, which limits the use of the formula to contractions the lengths of which in the direction of flow, are rather short. The reason for this will be shown in the discussion of the results of the experiments on short flumes. It is evident, therefore, that the sharp edge contraction, where very little drop takes place before the water passes between the sharp edges, is the condition most favorable to the application of the Weisbach formula, while the contraction with a gradually decreasing width, where all the water surface drop has taken place before the water passes the narrowest section, is the most favorable for the d'Aubuisson formula. For conditions between, where part of the drop takes place before the water reaches the most contracted section, and part occurs after this point is passed, the general formula applies. The contraction with rounded edges, where $H_3 > \frac{1}{2} D_3$, falls in this latter case, the value of H_2 not being the constant, $\frac{1}{3} D_1$, as in Formula (12), but a variable, as indicated on page 1176.

The coefficient, C_G, of the general formula considers only the contraction at the sides, since the contraction at the upper surface is taken care of by the term, H_2. One would expect, therefore, that this coefficient would have substantially the same value as that for orifices with the same class of edges. Thus, for those cases where the entrance is formed by gradual curves, this coefficient would approach unity, while, for sharp edges, it would approach the coefficient of a sharp edge orifice.

It may be reasonably assumed that, except for the contraction of that part of the stream above the tail-water level, due to the drop of the water surface before passing through the contraction, C_A and C_B in Formula (14) would be equal. If this is true, the term, H_2, in the general formula, accounts for the difference between C_A and C_B, and the coefficient, C_G, of the general formula should be equal to C_B, since

each is the coefficient due to contraction at the sides only. Assuming $C_G = C_B$, by equating Formulas (14) and (18), we have

$$C_G\left[H_3^{\frac{3}{2}} - H_2^{\frac{3}{2}}\right] = C_A H_3^{\frac{3}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

or,
$$\frac{H_2}{H_3} = \left[\frac{C_G - C_A}{C_G}\right]^{\frac{2}{3}} = \left[\frac{C_B - C_A}{C_B}\right]^{\frac{2}{3}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

From these assumptions, it follows, therefore, that the drop in the water surface at the "crest" of the sharp edge contraction is a constant proportion of the total drop. By inserting the values of C_A and C_B in Formula (20), $\frac{H_2}{H_3}$ is found to be 0.240 for the 1-ft. width, and 0.298 for the 2-ft. width. This agrees with the statement on page 1179 that the surface drop is greater for the 2-ft. contraction. In having the surface drop a constant proportion of the total drop, the contraction resembles the weir, the surface drop at the crest of which has been found to be a constant proportion of the head.*

Results on Experimental Flumes.

Short Flume with Rounded Entrance.—The results of the experiments on the short flume with rounded entrance are given in Table 4 and are shown by Figs. 11, 12, and 13.

The author regrets that he was prevented from completing the series of experiments on this flume, which he had planned, but as these few experiments throw considerable light on the theory of flow through a contraction, they will be fully described. The coefficients at the various observing sections for both the d'Aubuisson and Weisbach formulas are plotted at their respective distances from the entrance. A profile is given, showing the mean surface of the water as it flows through the flume. At each point along this profile is also shown the velocity head of the water at that point and the head lost in friction up to that point, which is, of course, the difference between the actual drop of the water and that part of this drop which is transformed into velocity. A line is also drawn showing at all sections the critical depth for a stream flowing with the velocity existing at that section.

An interesting difference between the flow through the short flume with rounded entrance and the contraction with rounded edges will be

* "Expériences Nouvelles sur l'Ecoulement en Deversoir exécutées a Dijon de 1886 a 1895", H. Bazin, 1898. Translated by A. Marichal and J. C. Trautwine, Jr., Assoc. Am. Soc. C. E., in the *Proceedings* of the Engineers' Club of Philadelphia.

noticed. At the end of the entrance section of the short flume, the surface drop is considerably less than the maximum drop in the flume. Although no actual measurements were made of the surface drop in the contraction with rounded edges, except in a few runs, no material drop was observed in the water surface after passing through the contraction. A possible cause of this difference is the constraining effect

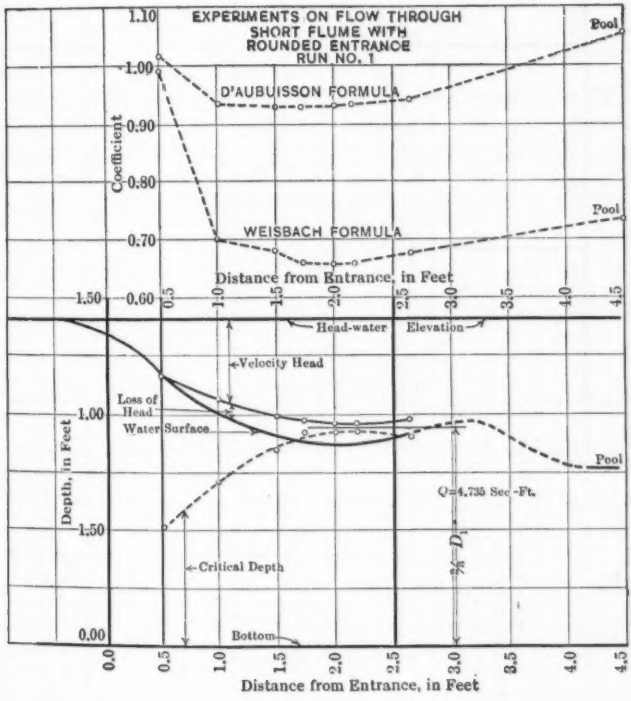

FIG. 11.

of the sides of the flume. In flowing through the contraction with rounded edges, or the entrance section of the flume, the water surface drops, and the water particles near it flow in a downward direction. Those near the bottom, however, flow horizontally. Because of their inertia, the particles tend to maintain their direction after passing through the converging portion. The path of the particles from above

intersects that of those from below, and each group tends to be deflected somewhat from the original direction. In the case of the contraction, the particles in the bottom portion are deflected laterally, while those above are given a more nearly horizontal direction. In the flume, however, because of the constraining effect of the sides, the lower

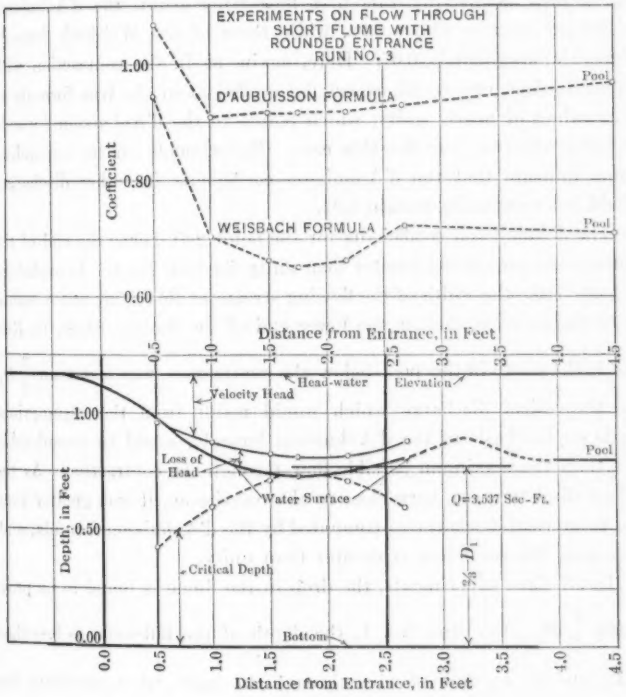

FIG. 13.

particles must continue in a horizontal direction and the particles above, therefore, cannot drop as rapidly as they would if those below could be deflected. The particles above, therefore, gradually acquire a more nearly horizontal flow as they pass down the flume, the lowest point in the water surface being reached some distance down stream from the entrance.

The coefficients of both formulas are found to have high values at the first measuring section of the short flume with rounded entrance. The condition of flow in this case is similar to that for which the general formula for contractions (Formula (18)) was derived, and, therefore, gives a high value of the coefficient when the assumption is made that the total drop is the same as the water surface drop at that point. Neglecting this first measuring point, the d'Aubuisson coefficients average about 0.92, while those of the Weisbach formula average approximately 0.67. Here, again, as in the contraction with rounded edges, one would expect the coefficient of the true formula to have values of nearly unity, which points to the d'Aubuisson formula as being the true one for this case. Experiments on the expanding flume indicate that the d'Aubuisson coefficients for other discharges would not necessarily remain 0.92.

The d'Aubuisson coefficients for the point 2 ft. below the end of the contraction vary, being greater than unity for Run No. 1. As explained on page 1162, the width of the flowing stream at this point was assumed to be the same as that of the lower end of the flume. Since, in Run No. 1, the depth in the pool below the contraction, was less than $\frac{2}{3} D_1$, the theoretical discharge which would result from the assumptions made on the basis of the d'Aubuisson formula, would be considerably less than the maximum possible flow through the contraction. As the actual discharge was very close to this maximum, it was greater than the theoretical discharge as computed by the d'Aubuisson formula, and, therefore, the coefficient is greater than unity.

In all three experiments, the drop in the flume is found to be practically $\frac{1}{3} D_1$. For Run No. 1, the depth of the tail-water is less than $\frac{2}{3} D_1$, and the water in flowing through the flume takes practically the depth which will give maximum discharge, or $\frac{2}{3} D_1$. That it does not take exactly this depth may be accounted for perhaps by the fact that, in spite of the smooth curves of the rounded entrance, there was some disturbance as the water entered the flume, and a considerable entrance loss, as is shown by the loss of head at the 1.0-ft. point. In Runs Nos. 2 and 3, the drop is also practically $\frac{2}{3} D_1$, although D_3 is slightly greater

than D_2. This would indicate a slight recovery of head, or change from velocity to elevation head, of the water after leaving the flume. This seems to have been accomplished in a stationary wave which occurred at the lower end of the flume. Just how much of the velocity head of the water can be recovered in the form of elevation head in this way cannot be determined from these experiments, but, in both cases in which it occurred, the recovery was slight. That the drop of the water surface in the flume should be practically $\frac{1}{3} D_1$ for cases where the depth of the tail-water is much greater than $\frac{2}{3} D_1$, is not to be expected.

In the short flume with rounded entrance, where the water reaches the depth $\frac{2}{3} D_1$ some distance up stream from the lower end, it is not possible for the flow to exceed $3.09\ W_2\ D_1^{\frac{3}{2}}$, as was the case for the contraction with rounded edges, as no expansion of the jet is possible immediately after the stream passes the lowest point within the contraction. The derivation of the theory, according to which the maximum flow is $3.09\ W_2\ D_1^{\frac{3}{2}}$, is based on the Bernouilli theorem, which, for open channels, assumes that each particle of water is subjected to a static pressure equal to the weight of the particles above it, up to the free water surface. When this condition does not exist, the maximum flow does not occur when the drop is $\frac{1}{3} D_1$. When the stream is free to expand laterally, its sides, as well as its upper surface, are at atmospheric pressure, and, therefore, all the particles within it are not subjected to the full static pressure due to the height of the water above them. Just how far up stream the effect of the reduction of pressure on the sides extends, is not easily determined, but it is probably dependent on the magnitude of this reduction. For small models such as those experimented on, it probably causes appreciable effect only a short distance above. From the foregoing, it will be seen that where the stream is free to expand after it passes the narrowest section, as in the contraction with rounded entrance, the discharge can exceed the "maximum", but in the short flume with rounded entrance, where the water surface reaches its lowest point some distance above the end of the flume, the "maximum" cannot be exceeded.

EXPERIMENTS ON FLOW
THROUGH SHORT FLUME
WITH SHARP CORNER ENTRANCE
. RUN NO. 1

FIG. 14.

Figs. 11, 12, and 13 show that the loss of head which occurs in the stream as it flows through the flume increases very little after the drop of the water surface is practically complete. This indicates that the loss took place in the curved entrance, and was, therefore, more of the nature of an entrance or impact loss, than a friction

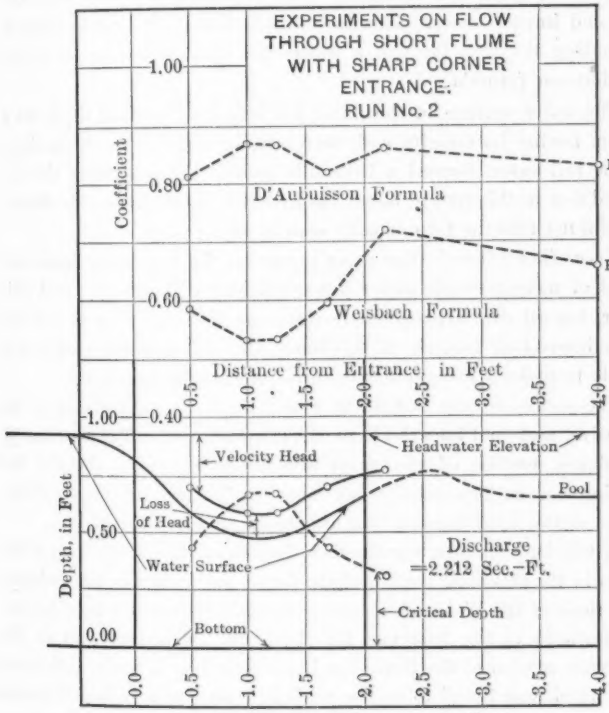

FIG. 15.

loss. If it was caused by friction, it would probably be greater in the narrow portion of the flume and would increase as the water passed down the flume.

Short Flume with Sharp Corners.—The results of the experiments on the short flume with sharp corners are given in Table 5 and shown on Figs. 14 and 15. The d'Aubuisson coefficients are fairly constant,

being between 0.80 and 0.90, while those of the Weisbach formula vary over a wide range. The d'Aubuisson coefficients are higher than one at first would expect, but it will be noticed that they are based on the actual area of flow, and, therefore, include the influence of the contraction resulting from the sharp corners only in so far as these introduce a somewhat turbulent state and thus cause internal friction and impact losses. This fact should always be kept in mind in estimating the flow through a contracted opening by the use of the d'Aubuisson formula.

The water surface in the flume fell below the critical depth for a stream having its velocity and, therefore, in order to reach the depth of the tail-water, formed a hydraulic jump. On account of the disturbed flow in this type of flume, the hydraulic jump was poorly defined, and did not take the form usually seen in such jump.

Expanding Flume.—The experiments on the expanding flume consisted of measurements under five conditions of head-water and tail-water, but all with approximately the same discharge. In view of the many interesting features of this flume, the writer regrets that he was unable to make a more complete series of experiments on it.

The results of the individual runs are shown on Tables 6 to 10, inclusive, and on Plates XIX to XXIII, inclusive, while a section of the flume, profiles of the water surface to natural scale, and the d'Aubuisson coefficients, for all runs, are shown on Plate XXIV. Views of two conditions of flow are shown on Figs. 16 and 17.

It will be seen that, for the first three runs, the d'Aubuisson coefficients in the prismatic section of the flume, are subject to less variation than those of the Weisbach formula, which indicates that the d'Aubuisson formula is the true one for this case. This coefficient in the prismatic section of the flume for Runs Nos. 1 to 3, varies little from 0.92, which was found to be the coefficient for similarly located points in the short flume with rounded entrance. As the expanding flume can be formed from the short flume with rounded entrance by adding the expanding portion, this agreement of the coefficients indicates that that portion has little influence on the flow through the narrow section of the flume. The high coefficient and negative loss of head at the 0.5-ft. point, and the great loss of head at the entrance, which occur in this flume, as in the short flume with rounded entrance, also point to this conclusion.

LANE ON
FLOW OF WATER THROUGH CONTRACTIONS.

In Runs Nos. 4 and 5, and to a less extent in Run No. 3, the wave formation in the flume made the determination of the coefficients difficult. These waves were stationary, maintaining the same location in the flume, and smooth, resembling wind waves on a deep body of water. A further resemblance to wind waves was shown by the formation of a stationary whitecap in Run No. 4. This formation could easily be mistaken for the hydraulic jump, but as the velocity was far below the critical value for that depth, it resulted from another cause. As will be seen in Plate XXII, this rolling water was preceded by two steep waves, and was due, no doubt, to the breaking over of the crest of a wave, when it became too steep, as in the formation of whitecaps.

In Runs Nos. 1 and 2 the drop of the water surface exceeded the theoretical drop, $\frac{1}{3} D_1$, by an appreciable amount. This is probably due to the loss of head at the entrance. The results confirm the theory of maximum flow, however, in so far as they show that the water surface under such conditions drops to a certain depth, which is independent of the depth of the water below the flume.

One of the peculiar features of this flume is that the flow through it, within certain limits, is not affected by variations in the tail-water level. The variation in discharge, depth above, and depth below, the flume, during the period in which these experiments were made, are plotted on Fig. 18, which shows that, during the first three runs, the depth above the flume varies very little, while the depth below is changed through quite a range, by the introduction of stop-logs in the channel. What variation occurs during this part of the period of experimentation, may practically all be accounted for by the variation in the discharge through the flume. When a certain tail-water depth was reached, however, this relation ceased, and any increase in the depth below, the discharge remaining the same, caused an increase in depth above the flume. This condition existed during Runs Nos. 4 and 5. The cause of these conditions can best be explained as an application of the theory of back-water curves.

The Theory of Back-water Curves as Applied to the Expanding Flume.

S. M. Woodward, M. Am. Soc. C. E., in the "Theory of the Hydraulic Jump and Back-water Curves"*, has defined a back-

* Miami Conservancy District, Technical Report, Part III.

water curve as "the profile of the surface of a stream of water in which all changes of velocity take place in accordance with Bernouilli's theorem." In that report are developed the possible cases of back-water curves in a channel of uniform width, both with and without

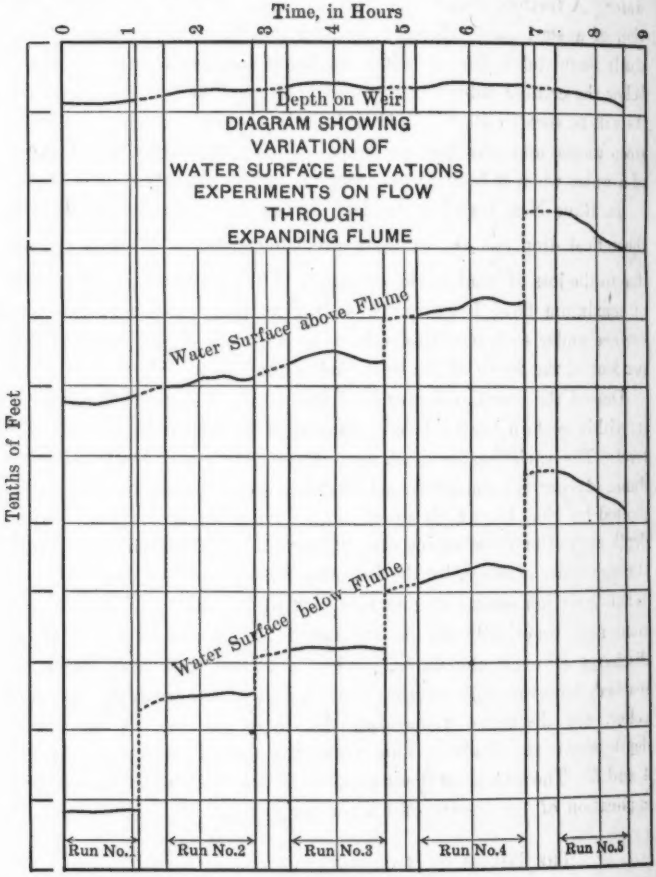

FIG. 18.

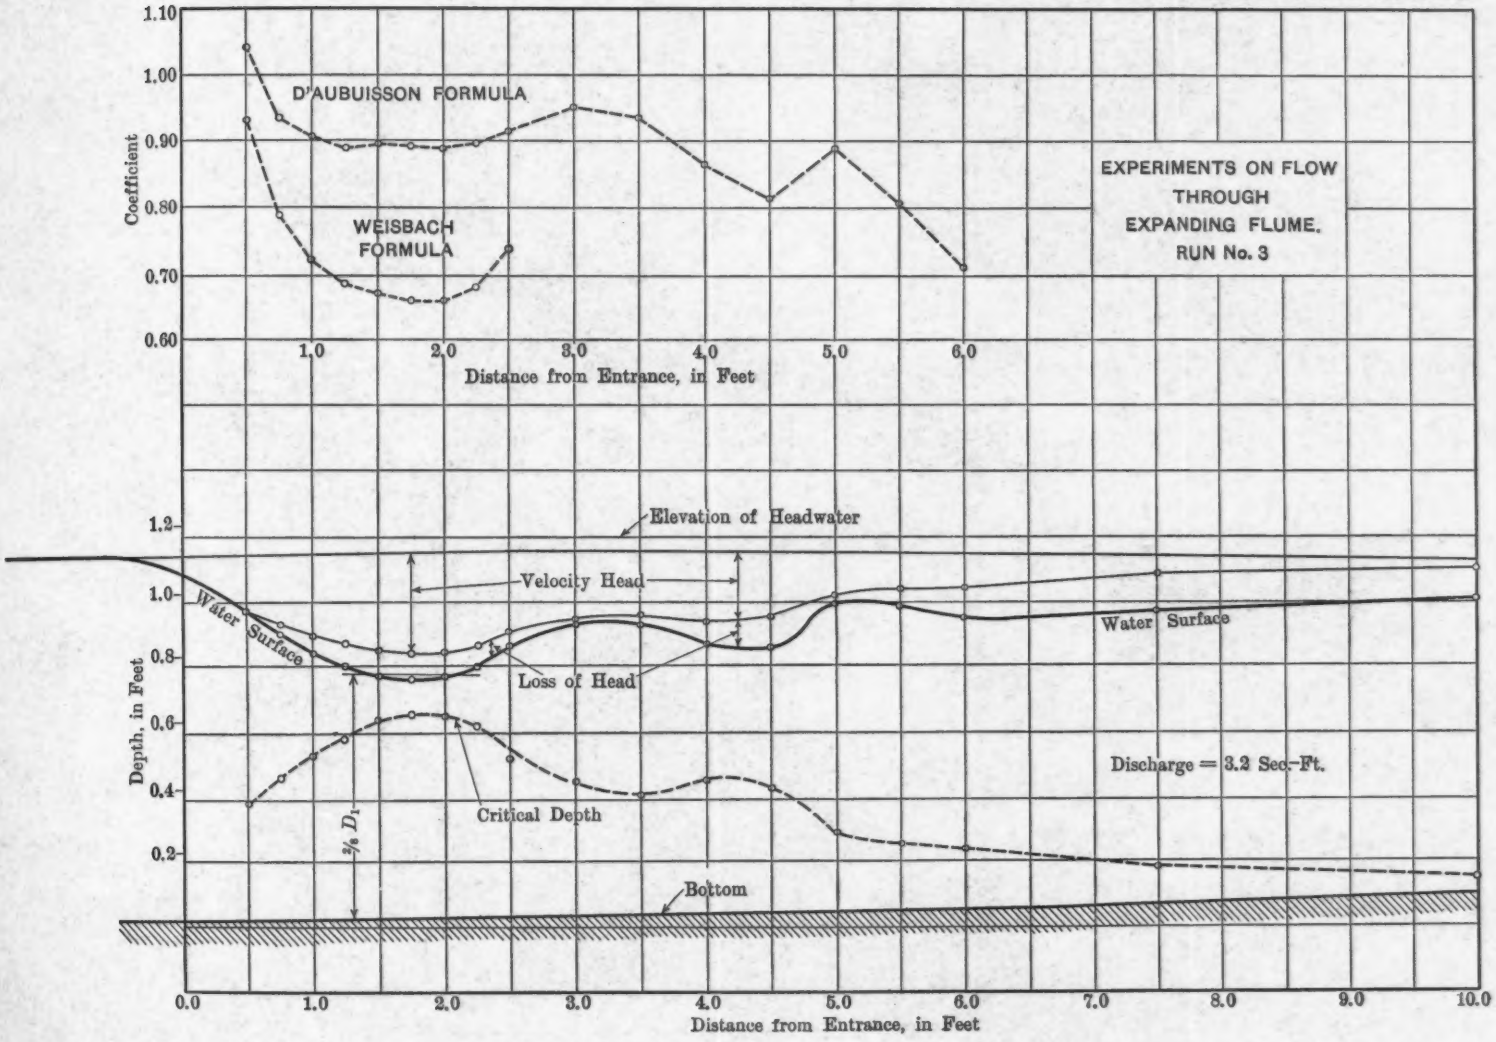
friction. As the friction loss in the expanding flume was relatively small, and as the theory of back-water curves, neglecting friction, is much simpler, the effect of friction will be neglected in this discussion.

PLATE XXI.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXIII, No. 1450.
LANE ON
FLOW OF WATER THROUGH CONTRACTIONS.



According to Mr. Woodward, there are five possible conditions of flow in a frictionless channel of uniform width. They are:

Case 1.—Bottom level; water surface level; any depth.

Case 2.—Bottom slopes downward; water surface slopes downward at a greater rate than the bottom; depth less than the critical value.

Case 3.—Bottom slopes downward; water surface slopes upward; depth greater than the critical value.

Case 4.—Bottom slopes upward; water surface slopes downward; depth greater than the critical value.

Case 5.—Bottom slopes upward; water surface slopes upward at a greater rate than the bottom; depth less than the critical value.

The critical value of the depth in the foregoing is that depth at which $V = \sqrt{g\,D}$.

Using an illustration given by Mr. Woodward, a similar list of possible conditions of flow in a frictionless channel of variable width, with level bottom, may be worked out. Fig. 19 represents such a channel, in which the width is varied in such a manner that with a flow of 2 000 cu. ft. per sec. entering the channel at *A*, and flowing toward the right, the water surface rises along the straight line, *AB*. The width of this channel decreases rapidly near the entrance, but less rapidly as the water surface rises, finally reaching a point of minimum width, beyond which it again increases. Any other smooth curve might be used to join the points, *CDE* and *FGH*, but, in this case, the surface profile would no longer be a straight line, but a curve. Since for all points along the channel, the sum of the velocity and elevation heads remains the same, at each point on both channels having the same surface elevation, the width would be the same.

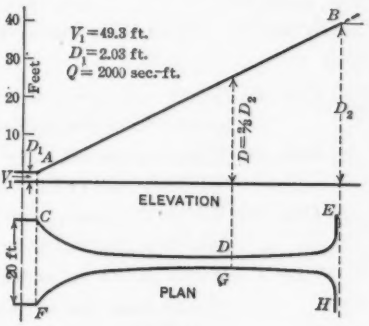


FIG. 19.

The point where the width is minimum can be found, as follows:

$$W = \frac{Q}{V\,D}$$

$$V = \sqrt{2\,g\,(D_2 - D)}$$

Differentiating, $$d\,W = d\left[\frac{Q}{\sqrt{2\,g\,(D_2 - D)}\,D^2}\right]$$

Equating to zero, and solving for D,

$$D = \frac{2}{3}\,D_2$$

From which, $$V = \sqrt{2\,g\left(\frac{3}{2}\,D - D\right)} = \sqrt{g\,D}$$

It will be seen, therefore, that the width is a minimum when the depth of the channel is at the critical value, as previously defined.

With the channel as shown in Fig. 19, the direction of flow might be reversed, the flow taking place from right to left. If the initial depth was D, and the quantity 2 000 cu. ft. per sec., as in the former case, the surface profile would be the same line, AB, the flow again being at the critical depths at the point of minimum width. In these two examples are shown the four possible conditions of flow in a frictionless channel with level bottom and variable width. They are:

Case 1.—Width increases; water surface slopes upward; depth greater than the critical value.

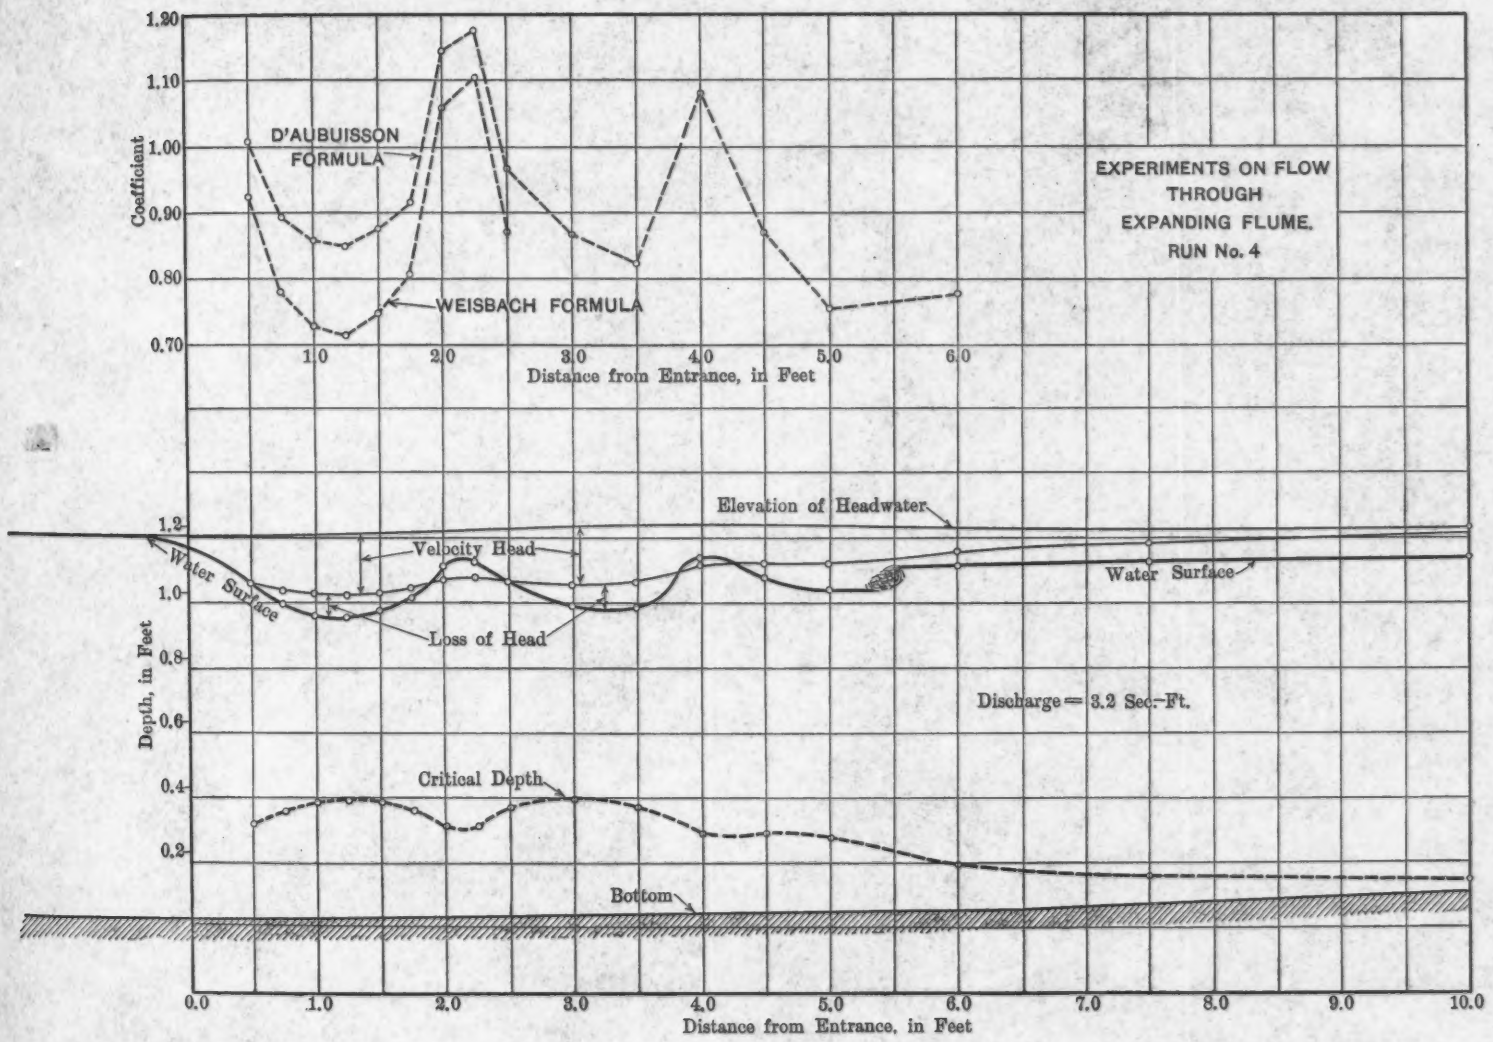
Case 2.—Width increases; water surface slopes downward; depth less than the critical value.

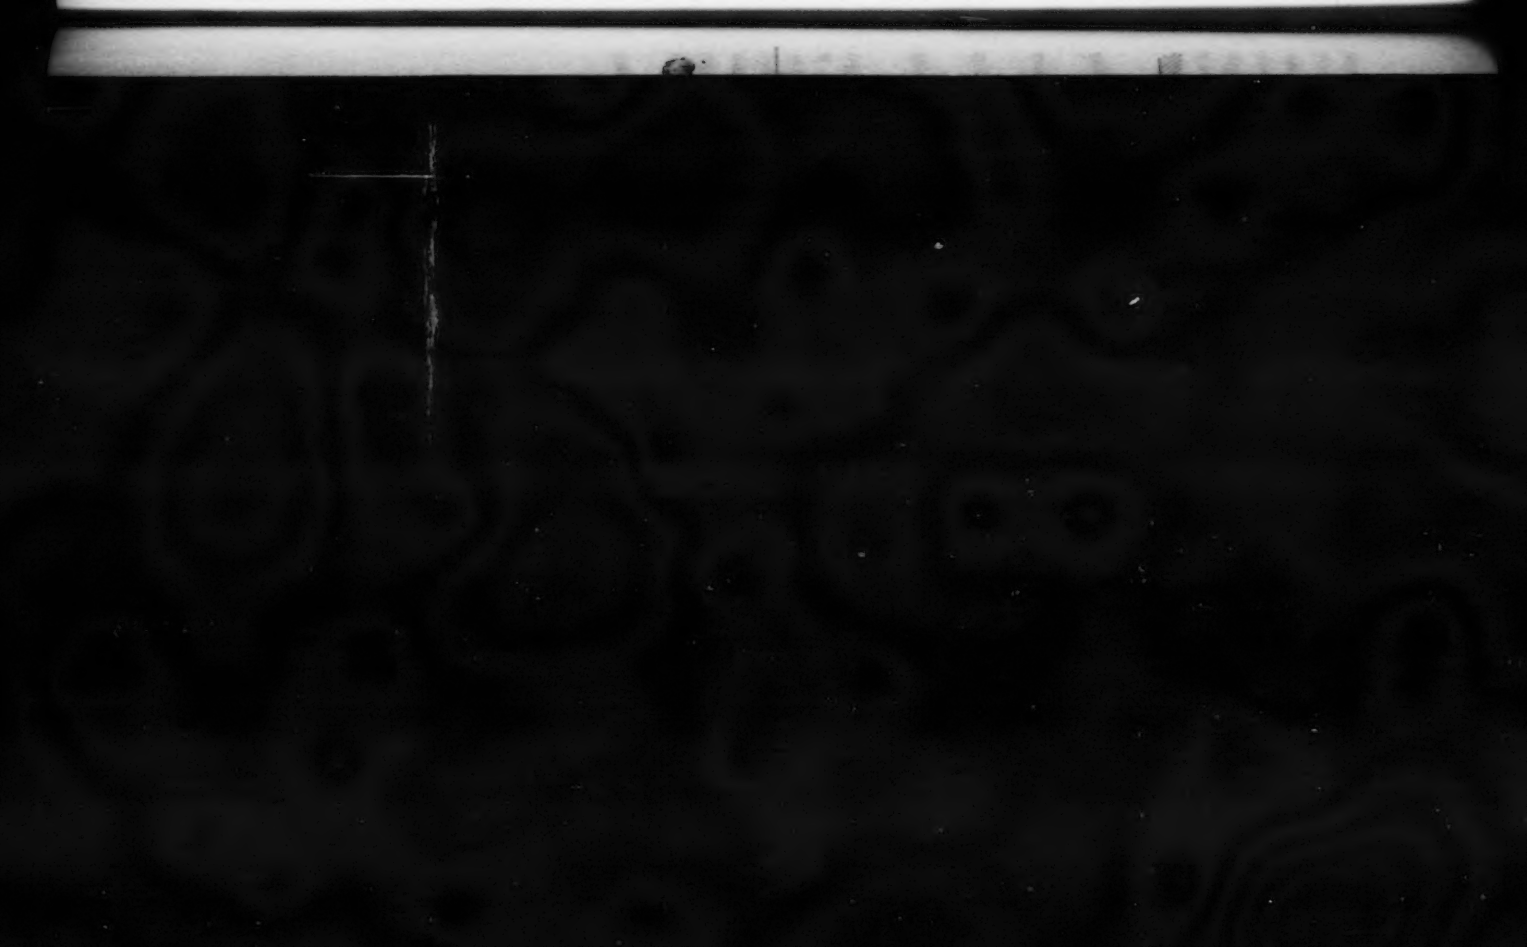
Case 3.—Width decreases; water surface slopes upward; depth less than the critical value.

Case 4.—Width decreases; water surface slopes downward; depth greater than the critical value.

The foregoing conditions may be applied to the flow through the expanding flume. As the depth of the water below the flume is independent of the shape of the flume, we will start at this elevation. In all the experiments, this depth at the lower end of the flume was great, with respect to the velocity at that point, and was, therefore, above the critical value. On Plate XXV is shown the theoretical and actual surface profiles for Runs Nos. 1 and 4. The theoretical

PLATE XXII.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXIII, No. 1450.
LANE ON
FLOW OF WATER THROUGH CONTRACTIONS.





profile has been worked out by the step method, on the assumption that the sum of the velocity and elevation heads at all points is the same, and that there is no friction loss.

In Run No. 1, according to Case 1, in an expanding channel, if the depth is above the critical value, the water surface must slope upward, as shown by the line, AB. This condition is possible, however, only when the flow is greater than the critical depth. In sloping upward in the direction of flow, and, therefore, downward from the tail-water level, this back-water curve soon reaches the critical depth. At this point, the curve ends, as it cannot go below that depth.

A method of locating the theoretical water surface above the flume is offered by the theory of maximum flow. According to this theory, the depth above may be computed by the formula, $Q = 3.09\ W_2\ D_1^{\frac{3}{2}}$. Knowing Q and W_2, D_1 may be computed. As the depth above the flume is greater than the critical value, from Case 4, it may be concluded that, in the entrance portion of the flume, where the width is decreasing, the water surface would slope downward. On reaching the prismatic section, from Case 1 for channels of uniform width, the water surface would be level. According to the theory of maximum flow, the depth in this section would be $D_2 = \frac{2}{3} D_1$, the velocity, $\sqrt{\frac{2}{3} g\ D_1} = \sqrt{g\ D_2}$, and, therefore, equal to the critical value.

Beginning at the lower end of the prismatic section, two curves are possible. If the water surface at this point drops an infinitesimal distance, the depth is below the critical value, and, therefore, from Case 2, the water surface must slope downward. (Line CD.) On the other hand, if the surface rises an infinitesimal distance, the flow takes place at greater than the critical depth, and, according to Case 1, the water surface must rise. (Line CE.) These two curves represent the "alternative stages" discussed by Karl R. Kennison, Assoc. M. Am. Soc. C. E.* Neither of these two profiles intersects the line, $A\ B$, and, therefore, if hydraulic phenomena were confined to applications of the Bernouilli theorem, the flow of the given quantity of water through the flume, with the given tail-water level, would be impossible. No phenomenon is known by which the water surface could change from the

* *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 347.

upper one of these curves and join the curve, AB, in a channel of the shape of the expanding flume. By means of the hydraulic jump, however, it is possible for the water surface to rise from the lower curve and join the curve, AB. The formula* for the hydraulic jump is:

$$D_2 = -\frac{D_1}{2} \pm \sqrt{\frac{2\,V_1^2\,D_1}{g} + \frac{D_1^2}{4}}$$

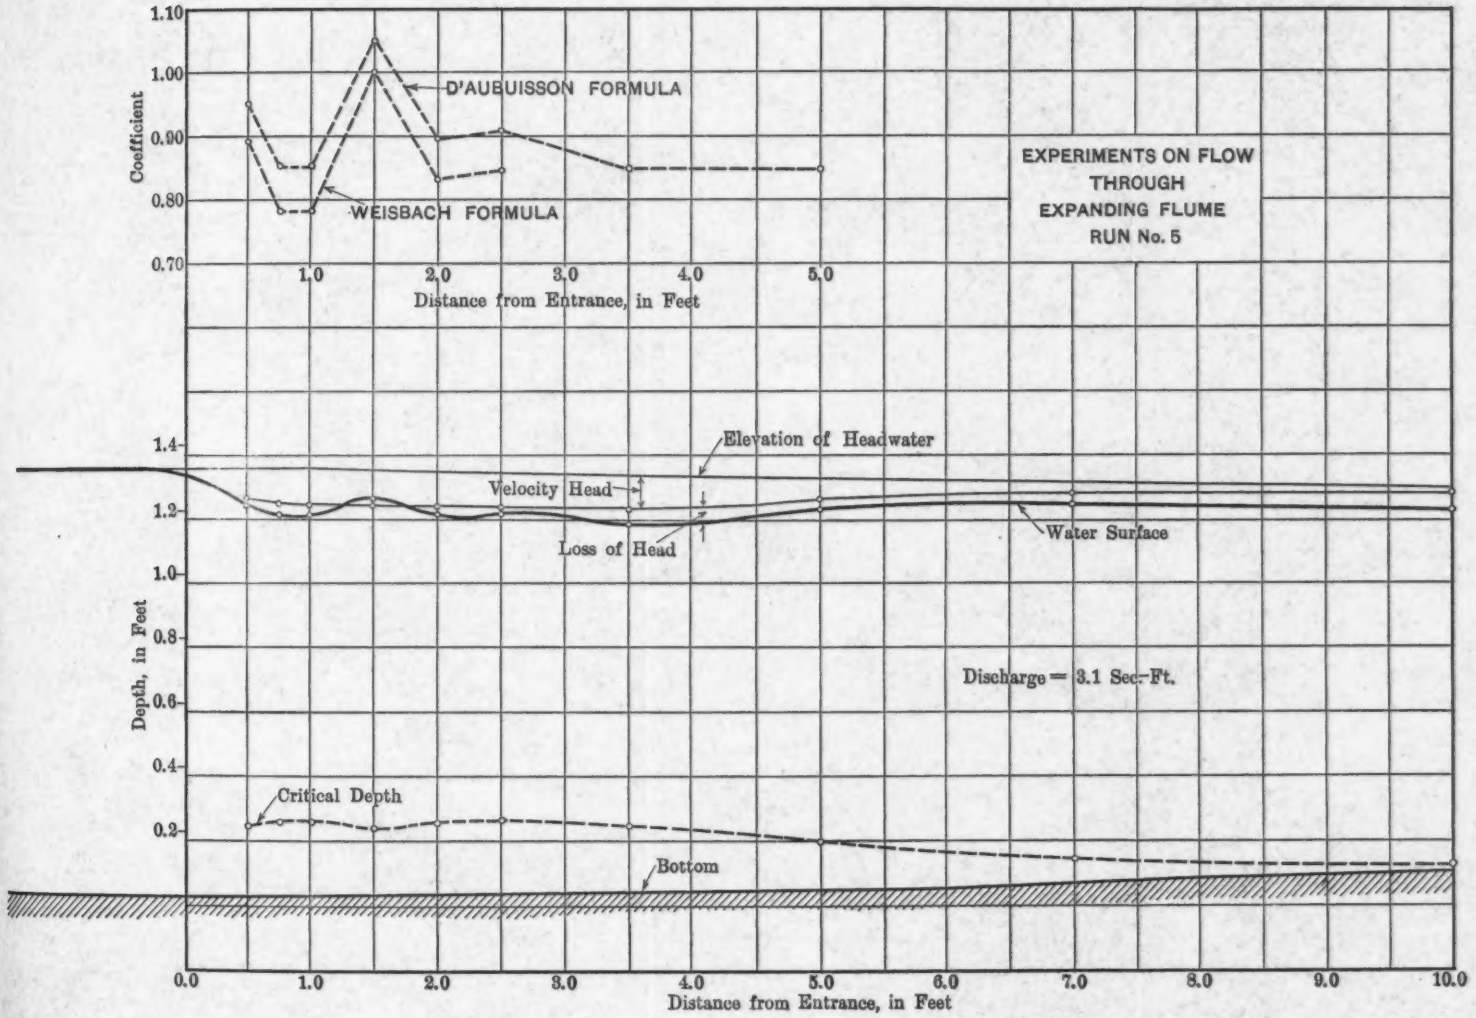
From this formula, it is evident that the jump can take place whenever $V > \sqrt{g\,D_1}$, or whenever the velocity exceeds the critical value. A jump might take place, therefore, at any point along the back-water curve, CD, as the flow is always at less than the critical depth. If a curve, FGH, is plotted above the curve, CD, at the height to which a hydraulic jump would take place, with the conditions of flow existing at that point, it will be found that this line intersects the curve, AB, at G. At this point, therefore, one would expect the water surface to rise in a hydraulic jump, from the line, CD, to the tail-water curve, AB.

The heavy line on Plate XXV shows the actual water surface for Run No. 1. Because of friction and impact losses, it starts at a greater elevation than the theoretical value. In entering the flume, it does not drop as rapidly as the theoretical curve, the reason for which has been explained previously. After the entrance water surface drop is complete, the profile follows closely the theoretical line, the jump taking place substantially as indicated by the theory, and the theoretical tail-water surface curve also agrees well with the actual surface profile.

A study of the theoretical back-water curves for Run No. 1 shows the reason for the different conditions of flow in the flumes, resulting from different tail-water levels. If the tail-water was at a lower elevation than the bottom of the flume, the flow in the expanding portion would follow the line CD, and drop off at D to the tail-water below. Until the water surface rose to the elevation D, the profile in the flume would be unchanged. As the water surface rose from D to H, it would still follow the line CD, and a phenomenon resembling the hydraulic jump would take place below the end of the flume. If the tail-water level is still further increased, the condition of flow in Run No. 1 would occur, the jump being formed in the flume

* This formula is usually accredited to Unwin, but according to Mr. S. M. Woodward, it was derived by a Frenchman, Belanger, in 1838.

PLATE XXIII.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXIII, No. 1450.
LANE ON
FLOW OF WATER THROUGH CONTRACTIONS.



itself. Below the jump, the surface curve would slope upward, as *BGA*, and above the jump, the profile would follow the line *CD*. The jump would occur at the point where the back-water curve connecting with the tail-water intersects the line of height of jump, *FGH*. This condition of flow occurs for all tail-water heights between *H* and *E*, the jump moving up the flume as the water level below it is increased. Runs Nos. 1 and 2 are in this class. When the tail-water level reaches *E*, the curve connecting with the tail-water follows the line *CE*, and intersects the height of jump line at *C*, the end of the prismatic section of the flume. The depth here is at the critical value, and, therefore, no jump can take place. Run No. 3 closely represents this condition. For all heights of tail-water below, and including that at *E*, the flow through the entrance and prismatic sections of the flume remains the same, being the condition of the maximum flow. That this actually occurred is shown on Fig. 18, by the comparatively constant head-water elevation of the first three runs, the slight variation being practically all due to the slight change of discharge.

As the tail-water level rises above *E*, the back-water curve connecting with the tail-water falls above the line *CE*, and does not reach the depth of maximum flow. When the condition of maximum flow exists, the head-water elevation is the minimum which will discharge the given quantity. It follows, therefore, that if the depth in the prismatic section is greater than that of maximum flow, the elevation of the head-water for the given discharge must be greater than this minimum. As the tail-water level is increased above *E*, if the discharge remains the same, the head-water, therefore, rises. This is the condition of flow in Runs Nos. 4 and 5.

The theoretical profile for Run No. 4 is shown on Plate XXV. The back-water curve in the entrance section follows Case 4, which, for a channel of decreasing width, the depth of flow being above the critical value, gives a downward slope. In the prismatic section, the profile follows Case 1, of channels of uniform width, being horizontal. In the expanding section, the flow is according to Case 1, for channels of variable width, and the water surface slopes upward. A comparison of the actual with the theoretical profile for this run shows that, except for the effect of the waves, the actual water surface profile agrees very closely with the theoretical profile.

New Water Measuring Devices.

Although the experiments described in this paper were not undertaken primarily for the purpose of developing apparatus for the measurement of flowing water, some of the devices experimented on possess considerable promise as measuring devices. This is particularly true of the sharp edge contractions and the expanding flume. Although the contraction with rounded entrance might be used for water measurement, all of its advantages and none of its disadvantages are found in the sharp edge contraction. The same is true with respect to a comparison of the short flume with rounded entrance and the expanding flume, the latter possessing all the advantages of the former, and other good points in addition. The few experiments on the short flume with sharp corners do not indicate that it has any particular value for measuring water.

The requirements of the ideal measuring device for irrigation purposes have been stated by Mr. V. M. Cone,* as follows:

"The ideal measuring device would (1) be inexpensive to construct, (2) be simple to operate, (3) require little maintenance, (4) be free from working parts, (5) be accurate in its measurement, (6) be free from sand, silt, or floating-trash troubles, and (7) require but little loss of head in the ditch."

The sharp edge contraction seems to fulfill all these requirements. It combines the advantages of the sharp edge weir and submerged orifice, without the disadvantages of either. A somewhat similar device has been developed by Mr. Cone,† but it requires greater fall in the ditch, as the water surface below the "weir" must be below the bottom of the approach channel.

To adapt the expanding flume to the measurement of water, it would be necessary, in addition to a gauge box in the channel above the flume, to connect a still box into the side of the flume about 2 ft. below the upper end, in order to read the depth of water in the throat. Although in most cases it would be necessary to read only the up-stream gauge, where conditions are such that no hydraulic jump is formed it would be necessary to read both gauges. A much simpler shape of flume might be devised, using the same principle as the writer's flume, but better adapted to working conditions. A flume of this sort has

* "The Venturi Flume", *Journal of Agricultural Research*, Vol. IX, No. 4.
† "A New Irrigation Weir", *Journal of Agricultural Research*, Vol. V, No. 24.

PLATE XXIV.

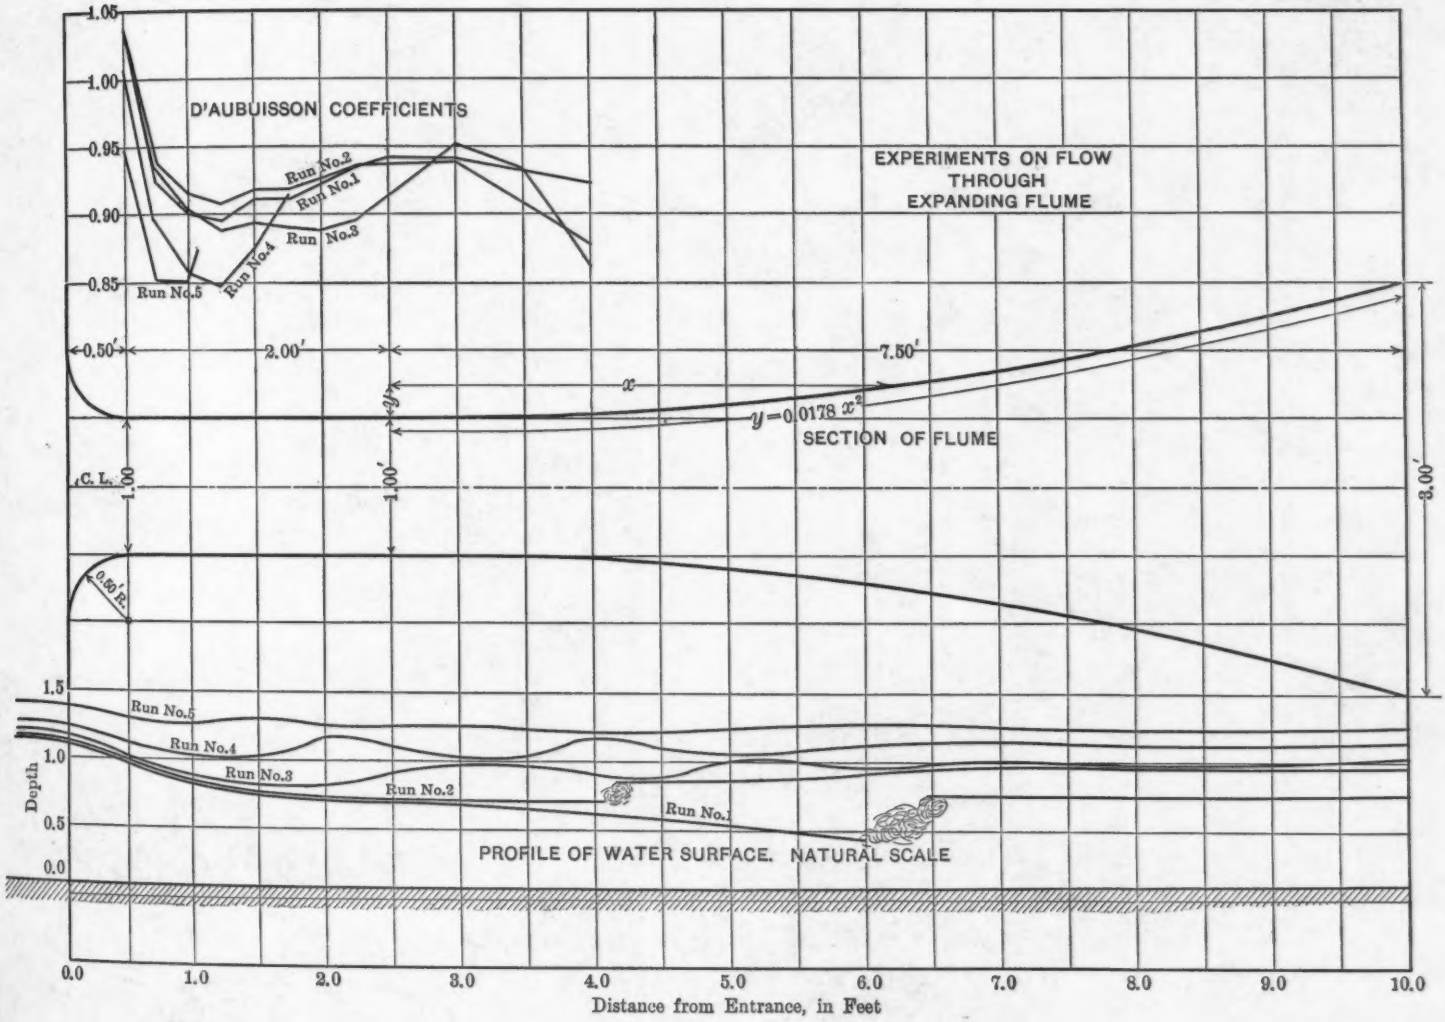
LANE ON
FLOW OF WATER THROUGH CONTRACTIONS.



been worked out independently by Mr. Cone, and described in his article on "The Venturi Flume", previously referred to. The experiments on this flume, however, covered only those stages where $D_2 > \frac{2}{3} D_1$. In limiting its use to this range, the writer believes that one of the important advantages is overlooked, namely, that the discharge at most stages is independent of the tail-water level. This feature makes the action of the expanding flume similar to that of the weir, while, at the same time, it is free from the silt troubles of a weir and requires much less loss of head. The writer very much regrets that he was prevented from carrying out a thorough test of this device, and would be glad to see it taken up by some one having the proper facilities, and developed into a practical measuring apparatus.

Conclusions.

In conclusion, the writer wishes to reiterate the common, but often neglected, warning of using formulas blindly in cases to which they do not apply, or beyond the limit of the conditions for which they were developed. This has been expressed by Mr. Woodward,* in the following words:

"Perhaps the most frequent error in hydraulic discussions, in general, is the very common one of applying a law, rule, or formula to a situation where it does not hold. Every rule in hydraulics is limited in its application to a definite set of conditions outside of which it may have no bearing whatsoever. This tendency to apply a perfectly good rule or formula to the wrong situation is naturally not only difficult to avoid in the first instance, but also not easy to refute by argument after the mistake has been made."

The number and diversity of the formulas considered in this discussion are indicative of the many conditions under which water may flow through a contraction in a channel. It is obvious that the application of any of them to all conditions, will lead to very erroneous results.

The d'Aubuisson formula is really an application of the Bernouilli theorem, with a coefficient to take care of the losses. The conditions in which it can be used are, in general, the same as those of the Bernouilli theorem. It can best be applied to contractions in which

* "Theory of the Hydraulic Jump and Back-water Curves," Miami Conservancy District, Technical Report, Part III, p. 11.

the water flows from one stage to another without a great deal of turbulence. The two areas of measurement must be the actual area of flow of the water, and the conditions at these points such that the static pressure on each particle is equal to the weight of the water above it, up to the free water surface. These conditions are fulfilled by the flow through the prismatic sections of the expanding flume and the short flume with rounded entrance, and also in the contraction with rounded entrance, where $H_3 < \frac{1}{3} D_1$. To a certain extent it can be applied to the short flume with sharp corners, the turbulence introduced by the sharp edges causing a lower value of the coefficient. It can rarely be applied where a reduction of velocity occurs, unless this reduction is gradual, as in several of the experiments on the expanding flume.

The conditions most favorable to the Weisbach theory are those existing at a sharp edge contraction of narrow width. The drop of the water surface above or in the contraction must be as small as possible, and the stream, after passing the contraction, must be free to expand laterally, since it is necessary that no pressure is exerted on those particles passing through the contraction above the tail-water level, in order that they may acquire a velocity corresponding to their distance below the head-water level. If the sharp edge contraction is wide, there will be a greater drop in the water surface above the contraction, and the formula will be less exact in its application. As the condition of flow in the case of a sharp edge contraction is very similar to that through an orifice or over a weir, the coefficients of both should be approximately the same.

On account of the surface drop which always takes place above a contraction, the condition assumed in the Weisbach theory will be only approximately attained. By modifying the Weisbach formula by giving different coefficients to that part of the flow above tail-water level, and that below it, a formula can be obtained, which will give results with a high degree of accuracy. The difference in the coefficients for these two parts is caused by the surface drop above the contraction, which reduces the flow through that portion above the tail-water level only. This formula is probably applicable to a great range of widths of the sharp edge contraction, and one may expect the coefficient, for that part of the flow below the tail-water level, to increase, while that for

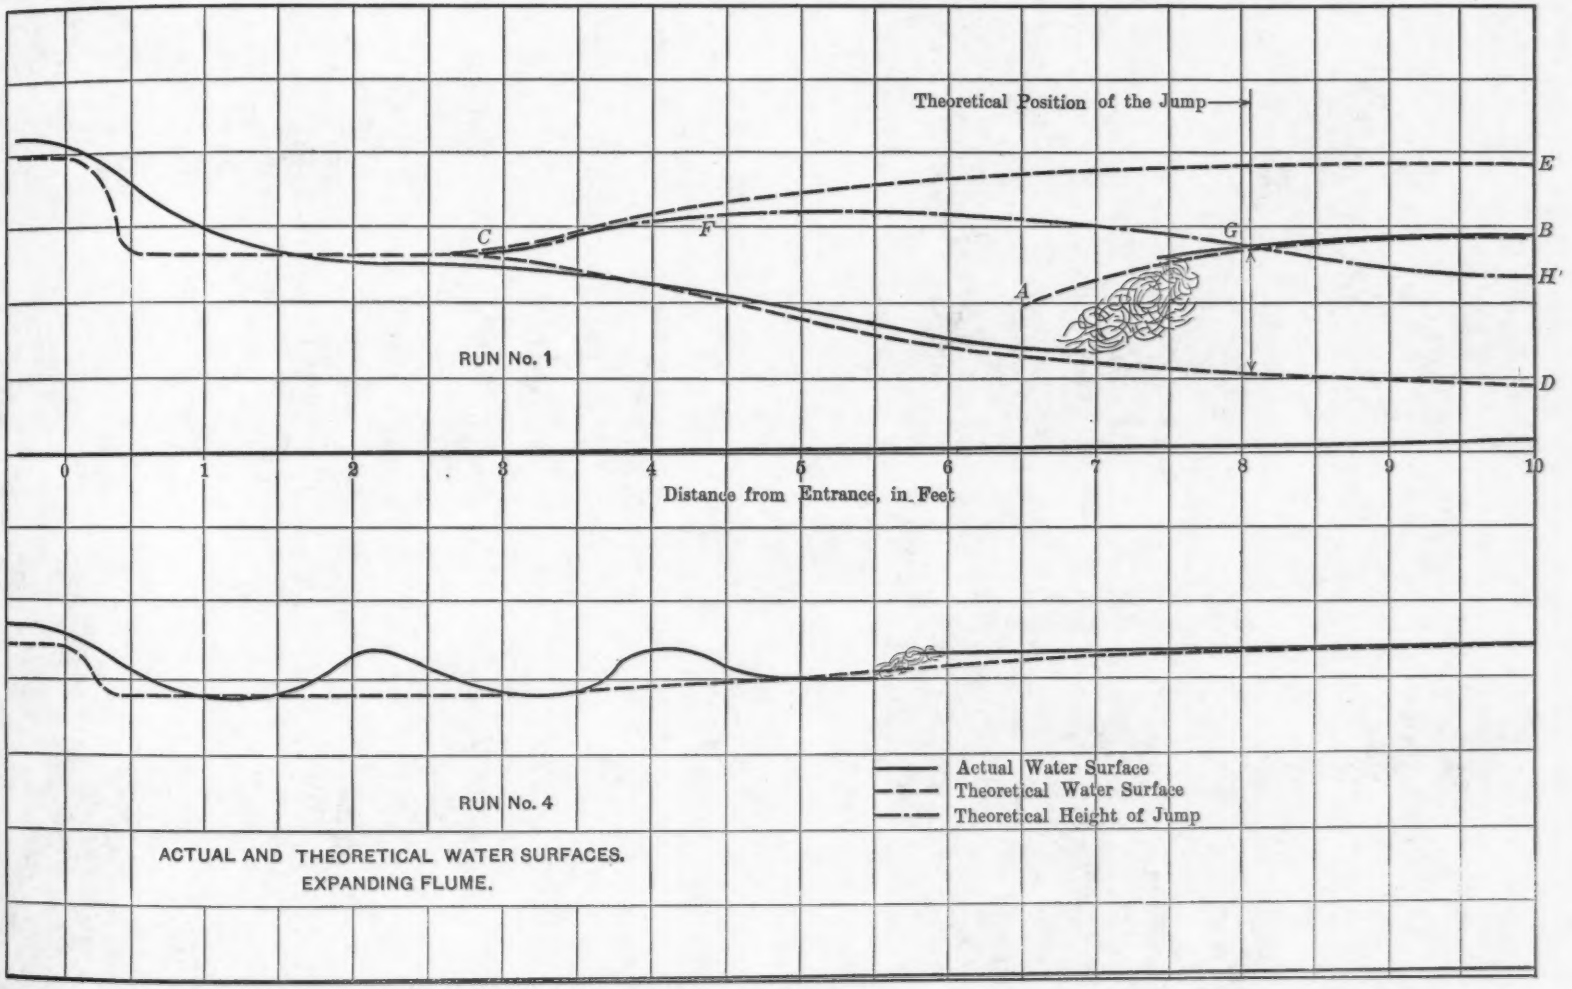
FLOW OF WATER THROUGH CONTRACTIONS.



ACTUAL AND THEORETICAL WATER SURFACES.
EXPANDING FLUME.

the part above the tail-water level decreases, as the width of the contraction is increased.

The general formula for contractions (Formula (18)) is adapted to contractions of short length, in which the stream is free to expand immediately after passing the narrowest point. This formula, in special cases, may take the form of either the d'Aubuisson or the Weisbach formula. The coefficients in it are substantially the same as those of an orifice of the same character of edges. This formula has the disadvantage that it contains the term, H_2, the drop of the water surface at the most contracted section, which is often difficult to measure.

Formula (12) is very similar to the general formula, but the term, H_2, of the general formula is replaced by the term, $\frac{1}{3} D_1$. For the contraction with rounded edges, where $D_3 < \frac{2}{3} D_1$, to which Formula (12) is applicable, H_2 is substantially equal to $\frac{1}{3} D_1$. For the contractions, the coefficients have been found to be a function of $\frac{H_3}{D_3}$.

The flow in the expanding flume follows very closely the theory of back-water curves. For a frictionless channel, with level bottom and variable width, the following four back-water curves are found to be possible:

Case 1.—Width increases; water surface slopes upward; depth greater than the critical value.

Case 2.—Width increases; water surface slopes downward; depth less than the critical value.

Case 3.—Width decreases; water surface slopes upward; depth less than the critical value.

Case 4.—Width decreases; water surface slopes downward; depth greater than the critical value.

A stream is flowing at the critical depth when $V = \sqrt{g D}$.

The condition of "maximum flow" has been found to exist substantially as indicated by the theory. The flow may exceed this "maximum", however, where the stream is allowed to expand at or immediately after the point at which the depth of maximum flow is reached.

The sharp edge contraction and the expanding flume are believed to possess value as measuring devices, and should be investigated further.

From Appendix II, it may be concluded that when a channel, in which water is flowing at high velocity, changes abruptly into a wider channel, with a bottom approximately level and at nearly the same elevation as that of the narrower channel, an unstable condition of flow may result.

ACKNOWLEDGMENTS.

The writer wishes to express his appreciation of the assistance of the following: To A. E. Morgan, and C. A. Bock, Members, Am. Soc. C. E., for encouragement in undertaking these experiments; to the Morgan Engineering Company and the Miami Conservancy District for the use of instruments, without which the experiments could not have been performed; to S. M. Woodward, and R. M. Riegel, Members, Am. Soc. C. E., Ivan E. Houk, Assoc. M. Am. Soc. C. E., and Mr. J. D. Burrage, for valuable suggestions and for assistance in preparing the manuscript; and to many of the Engineering Staff of the Miami Conservancy District, who, from time to time, assisted in the experiments.

APPENDIX I.

Application of the Theory of Flow Through Contractions to the Design of the Flood-Prevention Works of the Miami Conservancy District.

In the investigation for the design of the flood-prevention works of the Miami Conservancy District, one of the first problems encountered was that of the flow of water through a contraction in a channel. Soon after the flood had subsided, an extensive hydrographic survey was made to determine the discharge and slope of the river, and the area covered by the flood at its highest stage. It was found that a considerable drop in the water surface occurred at a number of bridges. The magnitude of the drop could be determined from the high-water marks and the area of the stream above, and, in the narrow section, could be easily measured. If the law relating to these areas, the drop, and the discharge of the stream, were known, a convenient method of determining the flood discharge was available.

The method of computing the peak flow from these measurements has been given in detail elsewhere,* and, therefore, will not be described here. The method used was devised by Messrs. S. M. Woodward and Ivan E. Houk. Essentially, it is the d'Aubuisson theory with a correction based on a computed friction loss. As the Weisbach formula was the nearly generally used form, these experiments were originally undertaken to compare the merits of the two theories. The results of these experiments show that, for the conditions at these bridge openings, the method used was much superior to the Weisbach formula.

Another case involving a determination of the drop which takes place at a contraction, arose in connection with the design of the retarding basins which are to be used in this flood-prevention system. Five large dams are being built across the Miami River and its tributaries to form basins for the storage of flood-water. Through these dams will be conduits, through which the ordinary discharge of the river will pass, but which are not large enough to discharge the flood flow of the river. The flow in excess of the capacity of these conduits will be retained in the basin above the dam until the flood peak is

* "The Official Plan of the Miami Conservancy District," Vol. I, pp. 67-71; Technical Report of the Miami Conservancy District, "Calculation of Flow in Open Channels," Part IV.

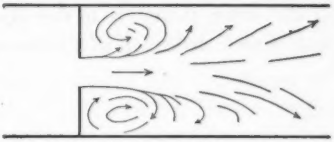
passed, and will then be discharged through the conduits into the stream again. In several of the dams, these conduits consist of large openings through a short spillway, which is a section of ogee dam, flanked at the ends by high concrete retaining walls. In order to take care of the flow of the stream during the construction period, it is proposed to build these walls first, leaving out the ogee spillway and conduit section until the earth section of the dam is complete. In times of freshet, all the water must pass through this comparatively narrow opening, and, in times of flood, considerable heading up will take place. As these dams are above populous cities, the backing up of the water to such an extent as to overtop the partly completed fill would be disastrous. In order to estimate accurately the height to which the water would rise behind the dam during a flood, a knowledge of the true laws governing the flow of water through a contracted opening was necessary.

To estimate the area and frequency of the flooding of land which will take place in the future, as a result of the construction of the detention dams, computations were made to ascertain the area which would have been covered by the floods that have occurred in the past. In several of these dams, the conduits are large, and as the floor of the basin is very flat, considerable land would be flooded in the basins before the water reached the top of these openings. In many of the smaller floods, the flow would never be sufficient to reach the top of the conduits. While the basins were filling to this point, the flow would take place through the conduits in the same manner as through a bridge in which the piers occupy a large portion of the waterway. Here, again, in order to determine the backing up which would take place, an understanding of this phenomenon of flow was necessary.

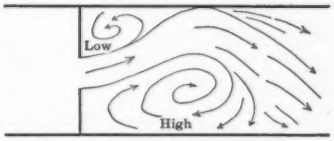
APPENDIX II.

Unstable State of the Stream from the Contractions.

Whenever a channel in which water is flowing at high velocity changes abruptly into a wider channel, with a bottom approximately level, and at nearly the same elevation as that of the narrower channel, an unstable state of flow may occur. The conditions under which this took place in the experiments on the contractions are shown in Fig. 20. When the water started to flow through the contractions, it passed down the center of the channel below, with a slight eddy on either side. (Fig. 20 (*A*)). This was an unstable condition, however, and soon the stream began to waver slightly and then was deflected to the side, as shown on Fig. 20 (*B*). This was a stable state, and the flow would continue in this position indefinitely. It was quite difficult to deflect it back into a central position again. At first, the writer thought that it was due to slight irregularities in the bottom, but as the deflection seemed to take place as often to one side as to the other, and as he had observed the same phenomenon in another apparatus under somewhat similar conditions, the conclusion was reached that this was not the cause.



(*A*)



(*B*)

FIG. 20.

When the stream from the contraction flowed in the center of the channel, the friction of this moving water on the quiescent water on both sides tended to draw this quiet water away from the contraction, making the tail-water level near the contraction lower than at some distance down stream. The water level on both sides of the flowing stream in this unstable state, was the same. The higher water down stream, however, tended to flow back toward the contraction, and if a slightly greater quantity flowed back on one side of the stream than on the other, the water level on that side became higher. The quiet water on this side, therefore, exerted a greater pressure on the flowing stream than the water on the opposite side, tending to force the flowing stream

toward the lower side. This allowed a larger quantity of water to flow back on the higher side, causing a still greater deflection, which increased until the position shown on Fig. 20 (*B*) was reached. The change of the flowing stream from a central position to a permanent deflection to the side of the channel was a matter of only a few seconds.

To remedy this condition, a low submerged weir was placed across the channel, 8 ft. below the bulkhead (Plate XVIII), which introduced a slight drop in the water surface at this point. The water surface below this weir was lower than the surface of the tail-water on the two sides of the stream, near the contraction, and there was no tendency of the water, therefore, to flow up the channel toward the contraction and cause a deflection of the stream.

DISCUSSION

Mr. Lyle.

WILLIAM T. LYLE,* ASSOC. M. AM. SOC. C. E. (by letter).—The conclusions drawn from these carefully prepared experiments are characterized by the cogency of their logic. The author regrets the fact that owing to the war his examination was not carried further. It is to be hoped that so profitable an undertaking may be continued, not only in the interest of hydraulic science, but also for the practical benefit of the profession. The author very properly calls attention to the folly of using hydraulic formulas beyond the limit of their application. A formula must be modified or changed whenever a new condition arises in the flow. The danger here involved has been forcibly brought home in the use of run-off formulas; but there are many other examples as well, and many a hidden rock on which professional reputations have been damaged.

Any device for contracting the cross-section of a jet or stream of water constitutes a measuring device. Thus, there are orifices, weirs, Venturi meters and contracted open channels. The underlying principle in them all is the hydraulic expression of the law of the conservation of energy, namely, Bernouilli's theorem—pressure head plus velocity head plus friction head is a constant.

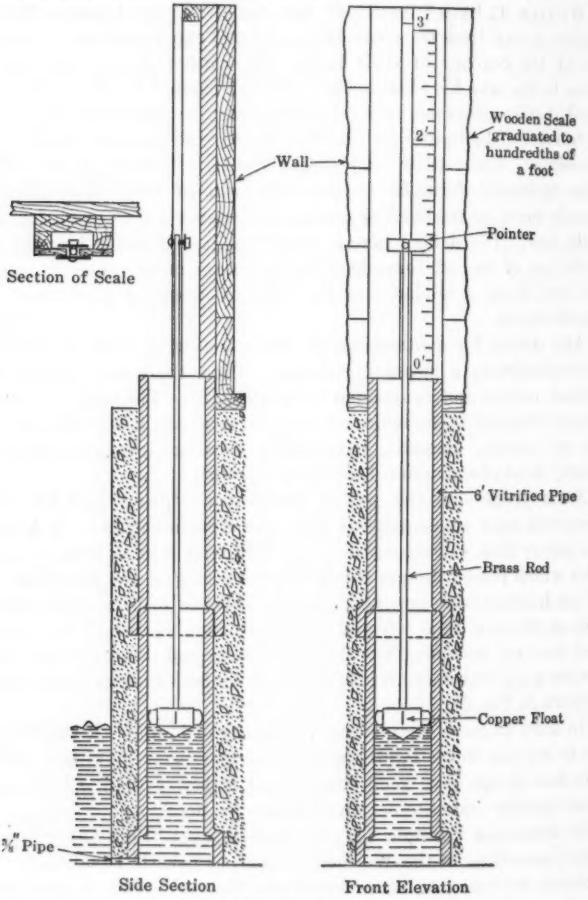
Some years ago, the writer designed a stilling box for use in volumetric tank measurements and weir determinations. It consisted of a copper float, convex on the lower side, with a brass stem to hold an index which passed up and down through a slot on the recording scale. All graduations were on wood which is believed to be a small improvement on the steel tape referred to in the paper because of the fact that wood does not corrode. The float moved up and down through a riser of sewer pipe, with a small hole for the entrance of water at the bottom, as shown in Fig. 21.

In order to guard against any possibility of binding, it was the practice to tap the index lightly with the finger before taking a reading. This float gauge gave good results and is better than a hook gauge, where rapidity and elimination of surge are necessary.

In discussing Formula (4), the author says: "Part (*b*) of the discharge, according to the Weisbach theory, is exactly equal to the total discharge according to the d'Aubuisson theory." This is true providing the coefficients are the same. The separate coefficients appear in Formula (14). The writer questions the strict applicability of Formula (12), which applies to orifice flow. This same equation appears in modified form again as Formula (18). The distinction made between stream line and turbulent flow is not well taken. The stream-line theory is now obsolescent, if not obsolete.

* Houston, Tex.

Mr. Lyle. The author very properly calls attention to the great advantage of the expanding flume over the weir for water measurement, the flume



FLOAT GAUGE

FIG. 21.

being free from clogging by floating matter, free from silt deposits, and requiring much less loss of head.

Mr. Henny. D. C. HENNY,* M. AM. SOC. C. E. (by letter).—Under the head of "New Water Measuring Devices", the author refers to the Venturi

* Portland, Ore.

flume suggested by Mr. V. M. Cone.* A somewhat different and equally simple device using the Venturi principle was suggested by the writer in 1915, for the purpose of measuring flow in irrigation laterals. It consists of an ordinary rating flume with parallel sides, the only addition being a thin, galvanized steel plate fastened to the sides, which depresses the water surface so as to contract the flow area to a throat, as shown by Fig. 22. Mr. Henny.

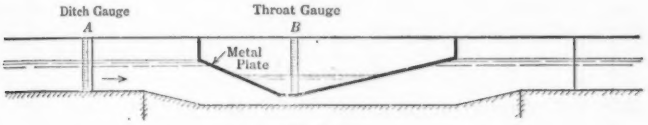


FIG. 22.

For ordinary irrigation heads of from 3 to 6 sec-ft., the throat is 4 in. high and 2 ft. wide, the throat velocity varying from 4.5 to 9 ft., with corresponding velocity heads of 0.31 to 1.26 ft. Two vertical staff

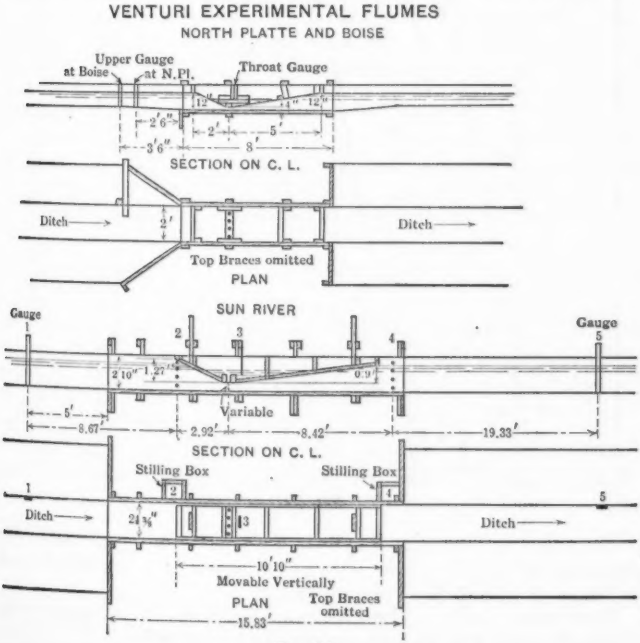

FIG. 23.

* *Journal of Agricultural Research*, Vol. IX, No. 4, April 23d, 1917.

Mr. Henny.

gauges, A and B, are read, the upper one placed in the ditch above the wings of the flume, the lower one in the head-water basin above the metal plate which communicates through small holes in the throat with the flowing water.

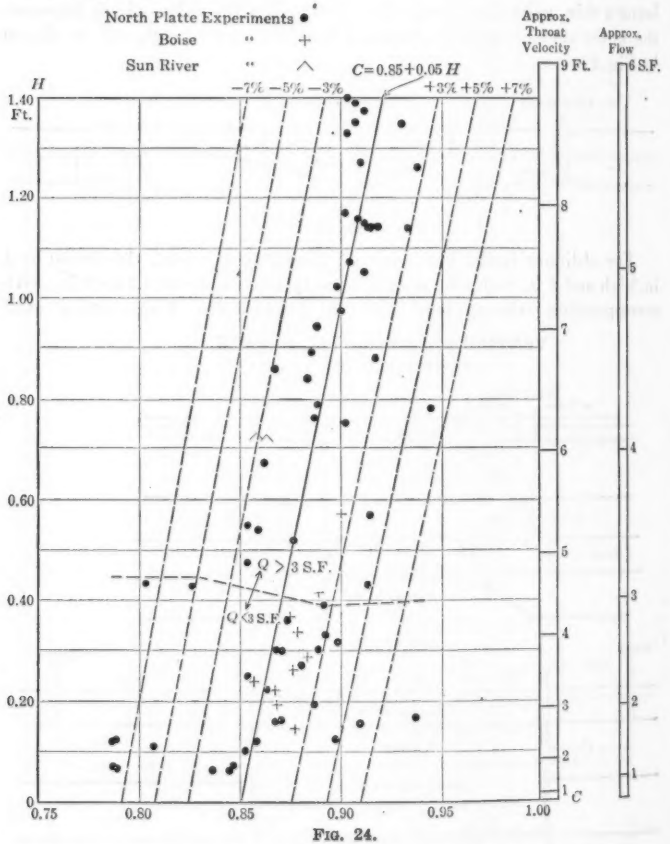

FIG. 24.

For a flow varying from 3 to 6 ft., the velocity in the approach ditch may range from 1 to 1.5 ft. Allowance is made in the formula used for the mean velocity head of approach.

Experiments made on three reclamation projects with flumes similar to that shown in Fig. 23, indicate that, in the formula,

$$V \text{ (Throat Velocity)} = C\sqrt{2\,g\,(H+h)},$$

in which H is the difference in gauge readings and h the mean velocity head of approach, the value of C increased with H. For the dimensions of flumes used in the experiments, the formula becomes: Mr. Henny.

$$V = (0.85 + 0.05\,H)\sqrt{2\,g\,(H + h)}$$

The flow thus determined in 39 experiments in which the throat velocity was 3 ft., or more, was compared with the flow measured by standard Cipolletti weirs with the following results (see Fig. 24):

35	measurements	show	error	of	less	than	3	per	cent.
3	"	"	"	"	"	"	5	"	"
1	"	"	"	"	"	"	7	"	"

These results appear to be quite satisfactory, considering that the weirs themselves are subject to error and that they represent three devices built and tested at widely separated points and by different experimenters.

The device is cheap, and the gauges can be easily read by an ordinary ditch rider. There is little danger of silting and the loss of head where flaring wings are used, both down stream and up stream, can be held down to less than 20% of the velocity head at the throat, or for the dimensions and maximum flow in question, to less than 3 in. The accuracy is not seriously affected by the usual range in variation of back-water.

Under certain conditions this form of Venturi flume is likely to be more accurate than the weir, partly because a small error in gauge reading has a smaller effect. It was intended, however, especially for cases where the available head is small or where the water carries considerable silt.

KARL R. KENNISON,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read Mr. Lane's valuable contribution to the literature on the subject of high-velocity flow in open channels, and has been particularly interested in the experiments in which the channel was given a smooth rounded entrance, producing a fairly smooth stable flow through it, with the internal pressure conditions in such channel not upset by a sharp-cornered entrance. Mr. Kennison.

One point which the writer wishes to make in this connection is that the quantity of discharge through a channel or conduit of this type may be governed by other conditions than the depth of water down stream, that each condition of flow must be studied by itself to determine just what it is that controls the quantity of flow, and that it is usually a simple matter to make this computation with remarkable precision, even when high-velocity flow and the hydraulic jump are involved.

* Boston, Mass.

Mr. Kennison.

The conclusion to be drawn from the experiments is a justification of the d'Aubuisson formula, in other words, the Bernouilli theorem. Everything in the experiments confirms this theorem and, consequently, justifies the computation of maximum discharge as the discharge at a depth equal to two-thirds the total net head, or twice the velocity head. Accordingly, if the down-stream head on the controlling section is less than two-thirds the total net head, it is too low to have any effect on the quantity discharged (through a channel or conduit long enough to contain a reasonably uniform flow). It is also true that the down-stream head can be quite a little greater than this two-thirds depth without materially decreasing the discharge. This characteristic of the water surface near the two-thirds depth has a tendency to create surface waves.

‡ Before velocity head is recovered (with, say, 20% loss) in expansion to 3 ft. width.

‖ Too low possibly to affect the discharge; hydraulic jump must occur.

§ Velocity head in flume, 19%, equivalent to discharge coefficient of a little less than 0.92.

¶ Use this depth if greater than effective down-stream head.

One point which should be borne in mind is that the undulating surface profile does not represent the pressure head on the water beneath the surface, as one might be led to expect from the author's computations and plotted results. The vertical height based on this undulating surface which he has marked "loss of head", and which appears to increase and decrease through the length of the channel, is not the actual loss of head. The actual loss continually increases and can never be recovered. The author's profile would have been clearer, if this loss of head had been plotted vertically down from the "elevation

of head water", in such a way as to show the net available head continually decreasing. Then the critical two-thirds depth instead of being plotted as two-thirds of the total original head, should have been plotted as two-thirds of the net head after subtracting this loss. This then would have shown a more remarkable coincidence between the actual depth in the channel and the theoretical two-thirds depth for a maximum unobstructed flow. Mr. Kennison.

To bring out this point more clearly, the writer has taken all those experiments in which the rounded entrance was used, has used a constant coefficient for this entrance of a little less than 0.92, which is the coefficient apparently indicated by the experiments, and has computed the discharge by analyzing each case separately, both with and without the expanding flume, disregarding entirely the down-stream water level when it is lower than the critical two-thirds depth. The computed results (Table 11), compare remarkably well with the measured discharge, undoubtedly well within the precision of the measurement of the discharge.

R. D. Goodrich,* M. Am. Soc. C. E. (by letter).—This paper is believed to be a most valuable contribution to the literature of hydraulic investigations and is certainly one of great interest to all engineers dealing with problems of river training and regulation, as well as to those interested in irrigation and power development. Mr. Goodrich.

The complete description of the plant and methods used, with the illustrations, give confidence in the accuracy of the tabulated data and the results shown. The Cippoletti weir is not usually considered to be as accurate a measuring device as the rectangular weir with suppressed contractions. However, in this case, where special experimental coefficients are used, there is little doubt as to the reliability of the measurements. The author's descriptions of, and comments on, the float gauges are of considerable importance, and it would also be interesting to know what led to the selection of the particular curve used for the sides of the expanding flume.

The experiments show conclusively that the coefficients in the two formulas investigated are far from constant. Although these coefficients vary with the nature of the entrance to the contraction, it is clearly shown that this variation is some function of the effective head and depth of the contraction and also in one case of the width. It is possible that the coefficients for rounded or other forms of entrance vary with the width, as well as those for the sharp edged contractions. The author's results on the two different widths of the sharp crested weir agree in this regard with the coefficients recommended by Mr. W. G. Beigh from his observations and measurements made in India, which approach unity as the width of the contraction increases.

* Tientsin, China.

Mr. Goodrich.

Although the author has treated this variation as linear and although Fig. 10 would indicate a straight line law for the sharp edged contraction, it does not follow that it would be so in all cases; C might be expressed by a relation of the form:

$$C = a + b\left(\frac{H_3}{D_3}\right)^n$$

in which the law becomes linear when $n = 1$, as for the sharp edged contraction. The writer found that with $n = 2$, a single equation could be found to express the probable variation in the d'Aubuisson coefficient for the round edged contraction, very nearly if not quite as well as the two equations given by the author. To do this, the writer subdivided the points shown by the circles in Fig. 7 into seven groups. The centers of gravity of these groups were then found graphically and their co-ordinates tabulated. The coefficients were then plotted against the squares of ratios, $\frac{H_3}{D_3}$.

It was found that a straight line passes practically through all except the lowest of these points. An equation could be written giving a reversal in the direction of curvature so as to make the curve pass through the center of this lower group and near the lowest isolated point by introducing a term in the form, $C\left(\frac{H_3}{D_3}\right)^n$, but there are not enough experiments with very small differences in depth to warrant this. The resulting equation is:

$$C = 0.877 + 0.32\left(\frac{H_3}{D_3}\right)^2.$$

This, however, is probably not the correct expression for the complete law of the variation in C, which should approach unity instead of a quantity less than unity, for very small values of $\frac{H_3}{D_3}$. For as H_3 decreases, it approaches the value of the velocity head as its limit. With any given value for Q, H_3 decreases with increase in A, which has the area of the channel of approach as its limit. In order that the value of Q may remain constant as H and A both approach their limits, it is necessary that C approach unity as its limit. It seems probable, therefore, that the variation of C is only approximately linear even for sharp edged contractions. In other words, the author's investigations, by demonstrating the variation of C, also demonstrate that neither of the formulas discussed represents the true law for the discharge of contracted sections.

The above simply illustrates another method of analyzing the results obtained and is not intended as a criticism of the author's investi-

gation. In fact, he brings out several characteristics in the formulas which might have been overlooked if he had used the method mentioned. Mr. Goodrich.

In discussing the sharp edged contraction, the author shows a very interesting relation between the d'Aubuisson and Weisbach formulas. In this connection the writer wishes to call attention to the statement made at the bottom of page 1176, that all the particles below the tail-water level have the same velocity. This assumption is used in the development of the Weisbach formula, but it does not agree with observations of velocities in open channels either above, below, or at gate openings and contracted sections.

The tendency of velocities in a vertical section of a stream to vary as the ordinates to a curve of more or less parabolic or elliptical form is too well known to be discussed here. It might be noted, however, that the rate of change of velocity is especially rapid near the bottom. The writer has measured velocities with a current meter above an open sluice-gate which showed a maximum velocity of approach of approximately twice the average, located considerably below mid-depth. The vertical velocity curve when plotted looked like an ordinary velocity curve inverted. All the observations taken at the several sections made showed the same conditions, and such "under tows" have been frequently observed. It is suggested that the words "theoretical velocity" would have given a more accurate statement for the author's purpose.

The author calls attention to the fact that the coefficients for the discharge above and below the level of the tail-water might be different, instead of being assumed the same as in the ordinary Weisbach formula, and further that the coefficient for the discharge below the level of the tail-water is the larger in the case of contracted sections, while for submerged weirs the larger coefficient applies to the section above the tail-water level. That this difference is due, at least in part, to the effects of contractions on the sides and surface, as explained by the author, is probably true. It may also be true that the depth of the thread of maximum velocity may influence these coefficients. It is certainly true that the maximum velocity and, therefore, the maximum discharge per unit depth, is nearer the surface above a weir than it is above a submerged gate; and the discharge through a contracted section is very similar to that through a partly submerged gate.

The high values of the coefficients for the discharge through both the short and the expanding flume are very noticeable and lead one to think that the coefficients used in practice are frequently too small. The author's discussion of the experiments on these flumes is most interesting, and his theories appear to be most reasonable and logical. They agree with some of the writer's observations and offer explanations for various phenomena for the first time, so far as the writer is aware. A case in point is discussed in Appendix II.

Mr. Goodrich. The writer has not devoted much study to the phenomena of flow through flumes and, therefore, is unable to discuss that part of the paper as he would wish. The paper is one to be highly commended and it is sincerely hoped that the author will soon be able to continue and enlarge upon his investigations, which have added materially to the knowledge of the undeveloped science of hydraulics.

Mr. Lane. E. W. LANE,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has been much pleased by the discussions on his paper and, particularly, by the constructive spirit which characterized them. He has always believed that a large part of the value of the papers presented to the Society results from the discussion by the members. No substantial disagreement was expressed with the conclusions, as given on page 1201.

The writer is pleased to note that Mr. Lyle's experience with float gauges agrees with his own. It is probable that they will come into wider use in the future, as their advantages are appreciated. Mr. Lyle evidently had in mind the stream-line theory, as used in certain text-book explanations of hydraulic principles, when he criticized the writer's reference to "the change from stream line to turbulent flow". The stream-line flow referred to is that which takes place at very low velocities, and is an observed fact, not a theory.†

Mr. Henny's experiments with a simple type of Venturi meter are interesting and show the high degree of accuracy which may be attained with such a device. The advantages of the flume type over the enclosed meter are that the former would be free from trouble due to floating trash, and, for most conditions, would require only one reading of head, rather than two.

Mr. Kennison rightly calls attention to the fact that the "undulating surface profile does not represent the pressure head on the water beneath the surface." The "loss of head" in Figs. 11 to 15 and Plates XIX to XXIII, was computed at each observation point in the manner ordinarily used in applying the Bernouilli theorem, that is, using the surface elevation of the water as the "elevation head" and the observed cross-sectional area in computing the "velocity head." The results obtained, in some cases giving negative loss of head, illustrate the danger of this procedure where stationary waves occur. Because of centrifugal force, due to the curvilinear motion of the water particles, pressures are induced in the water which make the pressure head of a point beneath the crest of the wave less, and that beneath the trough greater, than the elevation of the surface would indicate. This has been demonstrated experimentally in the investigations on concrete ships.‡

Mr. Lane.

Since the paper was published, the writer has made some studies which tend to show that the coefficients of the flume with rounded entrance and of the expanding flume are due to the curvilinear motion of the water particles in flowing through them. This, also, seems to explain why the flow takes place at less than the two-thirds depth. He hopes to publish these studies at a later date, when more experimental evidence is available.

In answer to the question raised by Mr. Goodrich regarding the curve used in the sides of the expanding flume, it may be said that the dimensions of the flume were chosen rather arbitrarily, the length, 10 ft., having been used as sufficient to give a gradual reduction of velocity, and the width at the lower end, 3 ft., to give small velocities at this point. A curve of such form that it would start tangent to the parallel sides of the flume at their lower end, and give a width of 3 ft. at the end of the flume, was chosen, the parabola having been selected arbitrarily, although an elliptical curve might have been as satisfactory.

The single formula, $C = 0.877 + 0.32 \left(\frac{H_3}{D_3}\right)^2$, developed by Mr. Goodrich for the round-edged contractions, is, perhaps, a better working equation than the two given by the writer. The latter were intended primarily to demonstrate the principles of flow involved, which, as has been noted, are not shown by the single formula.

It is possible that the coefficient for contractions approaches unity as the value of $\frac{H_3}{D_3}$ approaches zero. The experimental evidence gives no indication of this, however, and to do so would involve so rapid a change in the coefficient below $\frac{H_3}{D_3} = 0.1$, that it seems very unlikely.

The shape of the vertical velocity curve in the channel of approach would undoubtedly exercise some influence on the flow through the contraction, particularly when the velocity of approach is high. Its influence on the flow of water over weirs is known to be great. In the writer's experiments, however, the velocity of approach was low, and the head equivalent to this velocity was such a small proportion of the total head involved that its effect probably was not material.

Paper No. 1451

THE "LIGHT RAILWAYS" OF THE BATTLE FRONT IN FRANCE*

By Frank G. Jonah,† M. Am. Soc. C. E.

With Discussion by Messrs. William Wren Hay, F. W. Green, William M. Black, William J. Wilgus, H. F. Dunham, Morris E. Pumphrey, Hazen L. Hoyt, Jr., W. B. Poland, Marshall R. Pugh, Francis W. Perry, Gavin Hadden, and Frank G. Jonah.

Synopsis.

This paper describes the most recently developed method of transportation in the advance sector of an army.

The organization and execution of this work in the American Army was almost entirely in charge of engineers from civil life, many of whom were members of the Society. The object of this paper is to describe their activities and to present to the Profession one feature of the many engineering works that were executed so successfully by the Americans in France.

The following notes are the results of the writer's experience and observation in the construction and operation of "light railways" while acting as Major of the Twelfth Engineers (Railway), U. S. A., assigned to the British Army, and serving on the Picardy front (see Fig. 1) from August 21st to October 27th, 1917, and from that time until December 16th, 1918, as Chief Engineer of the Department of Light Railways of the American Expeditionary Forces.

The "light railway" was a development of the great war, and was gradually extended in scope and importance until, at the close of hos-

* Presented at the meeting of March 3d, 1920.
† Formerly Lt.-Col., Engineers, U. S. A.

tilities, the mileage of the lines ran into the thousands. These railways were among the principal agencies of transportation, having been, in fact, the link between the standard-gauge lines and the trenches.

It was found by the British, in 1916, that the transportation of supplies, essential for the dense concentration of men at the front, could not be accomplished satisfactorily on the highways, and that some supplementary means of conveyance were necessary; therefore,

FIG. 1.

orders were given for the development of a comprehensive system of "light railways" for the following primary reasons:

1st.—To relieve the highways of traffic. In addition to the wear and tear on motor transport and the excessive use of gasoline, the wear on the roads was leading to a heavy traffic in road material, so that a large part of the traffic hauled by motor trucks was road material (crushed stone or gravel)

to repair the damage which their own traffic was creating; and, consequently, there would be a great saving in labor in maintaining the roads if other means of transportation were developed.

2d.—To assist in a rapid advance over shell-torn areas when the roads were useless for motor transport and little better for horse transport.

3d.—To convey road material for the rapid repair of roads in the destroyed zones.

4th.—To reduce manual labor at the front.

The lines were developed so completely that, eventually, nearly all heavy material was transported by the "light railways", leaving the highways clear for light, fast-moving automobiles, trucks, and ambulances.

The rail-head, or terminus, on the standard-gauge line was usually 8 or 10 miles back of the front line—far enough to be out of range of the enemy's ordinary shell fire. Between the rail-head and the front, the standard-gauge line was generally destroyed by enemy operations, oftentimes as he retreated.

At the rail-head were concentrated the supplies for a certain sector, consisting of ammunition, rations, forage, road material, building material, fuel, barbed wire, fence pickets, concrete material, culvert pipe, plank, track material, tools—in short, everything necessary for the sustenance of troops and for their means of offensive and defensive operations; and it was the function of the "light railways" to carry these supplies to the forward battery positions and front line trenches.

The lines were also used in moving troops up to the front, bringing back the relieved troops to their rest areas and the wounded from the front, and extensive use also was made of them in salvage operations. The extent to which they were developed can be readily expressed by stating that for every mile of front which an army held, there were ten miles of light railway supplying it.

The gauge of track used by all the armies on the Western front, including the German Army, was 60 cm. (23⅝ in.), usually laid 2 ft. by the British and Americans. There was great advantage in this uniformity of gauge, as it permitted interchange of equipment among the

Allies and the immediate use of the captured German tracks after successful offensives.

In a general way, the characteristics of the lines on the different army fronts were similar. Grades of 3% and curves with a radius of 30 m. were freely used to facilitate rapid and easy construction. Embankments were made with 9-ft. crown cuts, with a 14-ft. base at sub-grade.

The French track was of built-up sections, 5 m. long, the rail weighing 9 kilos per meter, with steel ties, 1 m. long, riveted to the rail.

The British used a rail weighing 20 lb. per yd. A certain amount of track was laid in short sections bolted to steel ties, but the greater part was laid with rails at least 24 ft. long, on wooden ties, 4 by 6 in. by 4 ft. 6 in., as it was found that track laid on wooden ties was much more easily kept in line and surface than that laid on steel ties.

The American track was generally constructed on wooden ties, of rail weighing 25 lb. per yd., in 30-ft. lengths. A certain amount of track in built-up sections, with a rail, 5 m. long bolted to steel ties, was kept on hand for use at the extreme front. Sections of track in this length could be handled by a squad of men and coupled up without making any noise, and consequently were preferable for work near the trenches. Such sections also had advantages when building at night.

The German lines were built with rail weighing about 17 lb. per yd. on steel ties, bolted to the rails. They were extremely well built, and by reference to the map (Plate XXVI) showing the "light railways" on the Verdun and St. Mihiel Sectors, it will be seen that they had a greater mileage than the French and American Armies. Their extensive use of these railways was due to the fact that they were short of rubber tires and gasoline, and could not depend on motor transport to the extent that the Allies did; but they were in a position to develop steam railway transportation, as they held the coal and steel districts of France and Belgium.

The Germans had one type of built-up track, which had some advantages. One end of the 5-m. section had a pair of bars with a hooked projection, while the other end had the flange of the rail bent up. In laying track, the hooked bar engaged the bent-up flange of the last section. This enabled the track to be connected on the grade with great rapidity and without noise. Details of this track are indicated in Plate XXVIII.

The speed with which tracks could be constructed by the different Allied armies was practically the same. In September, 1917, the British stated that the construction of 1 mile of track, including ballasting, required 2 100 man days of labor. The "French Manual of Light Railway", issued in April, 1918, states that their average had been ¾ m. per man per day, which is equivalent to 2 146 man days.

Most Important American Line.

On the American front, the most important line, and the best constructed, was the connection between the central shops and storage yards at Abainville and the front line system at the Sorcy rail-head (see Plate XXVII), a line 18½ miles long, on which the average speed of construction was 2 640 man days per mile. As this line, together with the shops and yards at Abainville, and the Sorcy rail-head, was the most important light railway job constructed by the American forces, and as several interesting engineering problems were presented in their construction, they will be described in some detail.

When the American troops first went into the line in the St. Mihiel Sector, the base from which their supplies were drawn was Toul. As the French had troops in the line immediately east of the Americans, and were also using Toul as a base, it became congested, and the French suggested that the Americans build an independent rail-head at Sorcy, 11 miles west of Toul, which was done. This rail-head had the necessary facilities for transferring material from broad gauge to narrow gauge, and from car to motor truck; also warehouses, platforms, etc. It was regarded as very convenient, and represents a typical lay-out (see Plate XXVII).

From this rail-head at Sorcy, the American forces built a 60-cm. line to Cornieville (5 miles), where connection was made with the French system of light railways radiating from Toul. They also took over the operation of the French lines on the west half of the sector, St. Mihiel-Pont-a-Mousson.

The location for the central shops and storage yards of the "light railway" system was a matter for careful deliberation. Many sites were examined and reported on, the objections to most of them having been that they were either too close to the front, too far to the rear, too far to the left, or too far to the right. It was necessary to find a location that would afford ample space for a large yard, with standard-

gauge rail connection, and preferably canal connection as well. It was desirable also to have a location, at least, 30 km. back of the front line, as prisoners of war could be used if they were kept back that far; however, the Americans did all their work with their own troops.

Abainville, 2 km. north of Gondrecourt, was recommended by the writer, in March, 1918, as a suitable location for shops and yards, which recommendation was approved. Subsequent events proved it to be a most desirable location, as it was directly behind the St. Mihiel and Argonne fronts, on which the greater part of the American operations were conducted. Abainville was 35 km. back of the line, and was not within the area usually bombed by the Germans.

The shops were designed for the repair of "light railway" locomotives and gasoline tractors and for the assembly and repair of freight equipment; and the yards were designed for the storage of track and bridge material. The whole plant covered an area of 116 acres. The track arrangement was such that material coming up from the ports on standard gauge was unloaded in the storage yard and subsequently taken to the front, as required, on the "light railways".

The shop buildings consisted of the Austin type of steel building, and were erected by the American troops under the direction of a superintendent of the Austin Company, who had been sent over for that purpose. The buildings were of steel framework, boarded in with lumber obtained in France. The roof was boards covered with prepared roofing. The buildings were generally 40 ft. wide, 200 ft. long, and included an erecting shop, machine shop, gas-engine and auto repair shop, planing mill, two storehouses, car shop, foundry, blacksmith shop, power-house, and oil house.

Skillful Location Required.

In the construction of the line leading from these shops to the Sorcy rail-head, it was stipulated by the French authorities that there should be no grade crossings of the standard-gauge railways and no interference with navigation on the canals. These requirements necessitated skillful location.

The line was projected on the French standard contour maps 1 to 20 000, a study of which showed the feasibility of a line with grades not to exceed 3 per cent. An examination of the route showed that the necessary crossings of standard-gauge tracks could be made under

the main line viaducts or through large culvert openings. These points were selected as the governing conditions of the location, and the line was run accordingly. It was found that the French maps were extremely accurate—the summit elevations checked out exactly—the grade line and work was just what was expected.

It was necessary to cross the Marne-Rhine Canal at Void. The limited room for the 60-cm. line in this town necessitated crossing the canal at an angle of 68°, requiring a span of about 28 ft. to preserve the standard 6-m. width of waterway at right angles. Fortunately, the American engineers had some bridge stringers 8 by 16 by 28 ft., which had been sent over from the United States. The writer designed a counterweighted lift bridge (see Figs. 2, 3, and 4) with this material, which could be operated by one man. This proved so successful, that a standard plan was made for lift bridges, and as it was expected that most of the canal crossings could be constructed at right angles, a complete bridge was built and kept in reserve, the details for which are shown in Plate XXIX.

At Sorcy, it was necessary to cross the main line of the Chemin de Fer de l'Est, and as it was near the junction of the line from Gondrecourt with the main line, four main line tracks were crossed (see Figs. 5, 6, and 7). The railway at this place crossed over the canal, and the 60-cm. line was located to cross the standard-gauge tracks and canal at the same place. Fortunately, this crossing occurred in a cut, so that the line could be carried across with the minimum of bridging.

No girders or spans were available for this crossing, and it was necessary to design and build a bridge with the available material. It was found that two deck Howe trusses, with a few bents of trestle approach, would fit the conditions, give the necessary clearances, and would be the most practicable type of structure. These trusses were built of 5 by 10-in. road plank, and each truss weighed about 4½ tons. There was a locomotive crane working in the yard, which could lift 5 tons, so that after the bents were erected, the trusses were picked up by the crane and set in place in a few minutes. The whole bridge was framed and erected in five days, with no interference or delay to the traffic on the standard-gauge lines.

The Meuse River was also crossed by this line. At the place of crossing the stream was 125 ft. wide, with 14 ft. of water, and had very little current. Pile trestles were used in this case, as shown by Fig. 8.

BRIDGE OVER CHEMIN DE FER DE L'EST
AT SORCY STATION

The main line of the Chemin de Fer de l'Est was crossed in the Meuse River bottom through an overflow relief opening. A view of this structure is shown in Fig. 9, which is a good example of the splendid, beautiful, masonry structures which one sees everywhere on the French railways.

The types of engines and cars used on these railways are shown herewith. The Baldwin engine would handle 60 tons of freight up a 3% grade. The steam locomotives were not used up to the point where their smoke and steam would betray their presence to the enemy; some little distance back from the front lines they would be cut off, and the cars were handled to the extreme front by gas engine. The operating rules were extremely simple, and despatching was done by telephone.

Brakes	Hand brakes to all drivers

DISCUSSION

Mr. Hay. WILLIAM WREN HAY,* ASSOC. M. AM. SOC. C. E. (by letter).—It is not generally realized that the so-called "light railway" was carefully studied, and the standards of track and rolling equipment developed in Europe during the late '80s. Originally used by Decauville in his plant at Petit-Bourg, it was proposed by Col. Pechot (then a Captain of Artillery), as a means for the movement and supply of heavy siege artillery, and was the object of extended experiments and studies conducted by Col. Pechot, with the collaboration of M. Bourdon, a Government engineer, during the period 1881-89. The name "Pechot" survives in the Pechot locomotive, Type 1888, in the system of multiple-axle trucks used under heavy artillery pieces, and in various manufacturers' catalogues in the track described as "System Pechot."

In 1882-85, the track now known throughout the world as "Decauville" was developed by the company of that name and has served as the model for most of the track made in Europe, and its influence is readily traced in the United States. The system developed in France served also as a model for the Germans, and after tests conducted by them in 1891, was adopted in 1892, and standardized as Army equipment in 1897.† There is a record that as early as 1879 the Austrians had some narrow-gauge railway equipment for military purposes, but the writer is unable to determine when it was standardized for such use.

The Germans adopted the light railway for strategic use in times of peace, supplementing their standard-gauge railways toward their frontiers, but after trench warfare became fixed in the recent conflict, they developed a very dense system of narrow-gauge supply lines, particularly in front of Verdun and in the St. Mihiel salient, as is well shown on the map (Plate XXVI). So general was their use in the St. Mihiel area, that batteries and billeting areas on the slopes of steep hills were supplied direct from the main lines in the valleys by means of funicular tracks.

Originally, the writer believes, the French Army developed this material for use in connection with siege batteries and permanent fortifications, but it was soon realized that it was also of strategic, or tactical, value, and considerable experience was gained by them in connection with the military railways built in the French Zone, in Morocco. From press reports, the French had at the beginning of the war about 870 miles of 60-cm. track, with 60 locomotives and 350 cars. At the signing of the Armistice, this had been increased to almost 2 500 miles of track, 900 locomotives, and 4 500 cars. The American forces were reported by the Chief of Engineers to have been operating 1 390 miles of

* Forest Hills, N. Y.

† *Le Genie Civil*, Vol. 72, p. 449 (June 22d, 1918).

Mr. Hay.

track, of which about 1 080 were captured German lines, 165 locomotives of all classes, and 1 695 cars. The writer has seen no statement of the mileage of either the British or German lines.

Contrary to the text, both the French and German standards for portable track are for rail weighing 9.5 kg. per m. (about 19 lb. per yd.), in both cases attached to eight rolled steel ties per 5-m. length, the German track being clip-bolted as shown, the French cold-riveted to the ties. The usual French rail has a greater base than height, while the German rail has a greater height than base. During the war, many sections were in use. These can be compared with the equal base by height standard 20-lb. rail used by the English, and the standard American 25-lb. section. The axle concentration on this track was not allowed to exceed 3 500 kg. for 0-6-0 type locomotive loading. (In this connection, the conclusion reached by British engineers in India was to allow 3 long tons—about 3 000 kg.—for the concentration on 20-lb. rails, 24-in. gauge track).

The Pechot locomotive has received a great deal of publicity since the opening of hostilities in 1914. It was originally developed for use in and around fortifications, where sharp curves and steep grades were necessary, and probably rendered its most notable service on the steep hillsides in and around Verdun, the very service for which it was intended. The trucks are of the suspended, articulated type. The firebox is double, with a single grate, and designed so that for all grades less than 10% it is constantly submerged. The interesting thing to the general public is that this locomotive is double and "works both ways". The grate area is too small for heavy service. These locomotives are very expensive compared to other types.

A locomotive of the Mallet articulated type, 0-6-6-0, was built in Europe before the war and received some use in Morocco and on fortification construction, but whether any was used on the light railways of the battle front the writer never heard. The majority of the locomotives used by the French were the Decauville 8-ton (empty), 0-6-0 type, developed from the experience gained in Morocco.

Mr. Green.

F. W. GREEN,* M. AM. SOC. C. E. (by letter).—The author is to be congratulated on the thorough and comprehensive manner in which he has treated this interesting subject. Although much has been written on various other activities incident to the conduct of the war, very little has been done in the way of description of the construction and operation of the "light railways." This paper, therefore, presents to the Profession a subject comparatively new; and although it relates to the application of the light-railway principle to military operations, the civil engineer will not fail to observe its availability for a number of purposes, in which it may prove to be more economical than practices heretofore followed.

* St. Louis, Mo.

Mr. Green. While serving with the Third British Army as an officer of the Twelfth Engineers, in an endeavor to discover the *raison d'être* of the "light railways", the writer was informed that the experiences of the winters of 1914-15 and 1916-17, especially the latter, clearly indicated the danger of military reverses involved in an adherence to the use of motor lorries for transportation between rail-heads and battle front. With the unprecedented density of men in the battle lines, transportation by motor transport involved chronic congestion, with consequent decrease in mobility, as well as the diversion from combat duty of large numbers of men required to keep the highways passable. It was felt that the saturation point had about been reached when the damage done to roads by motor trucks hauling road repair material almost offset the benefits accruing to the road by the use of said material.

In casting about for means of ameliorating these conditions, attention was called to what the French styled the "Decauville" railway, usually of 1-m. gauge. The British decided to adopt a gauge of 60 cm., because of considerations of greater mobility, less cost, and inability of the enemy to connect up with it and use it in case of retirement before it could be removed.

The writer recalls having observed the use of light railways in certain large manufacturing plants, notably steel mills, as long ago as 25 years. It is not known whether that was another application of the "Decauville" principle, or a mere coincidence.

Early in 1917, light railways were started experimentally behind one of the British Armies. Their success was so immediate that by the summer of that year the larger percentage of transport between broad-gauge rail-heads and the battle front was changed from motor lorries to the light railways. The writer was informed by a British officer that about 18 miles of single-track light railway operation in the Gouzeaucourt sector permitted the abandonment of the operation of more than 600 motor lorries and the retirement from road maintenance labor forces of more than 3 000 men.

In the back areas, steam locomotives were used; where under enemy observation day and night, gas or gas-electric tractors were utilized. In the design of the steam locomotives, the saddle type of water tank was provided, presumably because of the additional adhesion available for tractive effort. Whatever advantage thus accrued was, in the writer's opinion, more than offset by the decreased stability against overturning resulting therefrom. As these locomotives were "shopped", the saddle tanks were sometimes removed and mounted on a trailer type of tender behind the locomotive, and it was remarked that the tendency to derailment was very much reduced.

Mr. Green.

It is believed that there is a large field for the development of this type of transportation in the United States. A great amount of highway construction is now under way in many States. The transport of road material from broad-gauge railway cars to the point required on the work by gas or gas-electric tractors and self-dumping equipment should prove much more economical than by the use of teams. Similarly, there are large areas of hardwood timber suitable for railway cross-ties and other purposes, which heretofore have been considered beyond the limit of commercial exploitation. The light railway, cheap of construction and maintenance, the track of which can be used over and over again with small cost of removal, ought to find a field for development in such cases.

The author undoubtedly gave much more thorough consideration to developing his design for the rail-head at Sorcy than is usual under war-time conditions. As a result he succeeded in obtaining the most complete and practicable layout the writer has ever seen. In the stress of war it is quite common for such layouts to be made to fit the ground with a minimum of construction effort, without regard to convenience and facility of operation.

In the design of the lift bridge at Void, the author has demonstrated not only the resourcefulness with which American civil engineers applied themselves to the solution of military problems, but also that Mars and Apollo follow different paths.

The Howe trusses over the Eastern Railway at Sorcy, however, are evidently the result of very careful and conscientious designing, and when considered from the standpoint of military engineering, are unusually pleasing to the eye. The location of the line from Abainville to Sorcy also shows that much thought and study was given to it, and Col. Jonah is entitled to much credit for the successful results obtained.

Mr. Black.

WILLIAM M. BLACK,* M. AM. SOC. C. E. (by letter).—In the introduction to his paper, the author states that the execution of the light railway work was almost entirely in charge of engineers from civil life. At this time when the necessity for universal military training for our citizens is under consideration, and, further, while some members of the Society are advocating the removal from the charge of the Corps of Engineers of the Army of the civil works from which alone the officers of that Corps were enabled to obtain practical training in time of peace in the organization and conduct of important engineering works—with the development of character which results from such responsibilities—certain comments on this statement are pertinent.

At the outbreak of the war, in accordance with the traditional policy of our country, the United States had available a pitifully small number of trained soldiers by whom her great man power could be instructed and made useful for the struggle into which she had been forced.

* Maj.-Gen., U. S. A. (*Retired*), Washington, D. C.

Mr. Black.

On April 10th, 1917, there were only 256 engineer officers in the Regular Army. In the National Guard, the Engineer Service had been neglected, and even in the few engineer units of that service many of the officers were not engineers. During the war the number of regular officers was increased to 449, partly from graduates of the United States Military Academy and partly from young graduates of civil technical schools. Of these regular officers, 94% were engaged in military duty during the war. Of the remainder, the majority were physically unfit for field work. They, assisted by engineer officers on the retired list and the United States Assistant Engineers, kept the civil works in charge of the Corps in uninterrupted operation. At the outbreak of the war, the total enlisted strength of the Engineers of the Regular Army was 2 228, organized into 15 units. The necessities of war required the expansion of the above to 473 units, comprising 284 983 men. The number of commissioned officers was increased to 10 886.

It is manifest that this great expansion could not have been accomplished efficiently without the aid of the civil engineers of the country. This aid was rendered promptly and willingly, and the final success of our operations in France is manifestly due greatly to their efforts; but is there a man of all this number who did not regret that he had not had previous training, at least in matters of army organization and administration? Was it not a difficult task for many to merge their individualities in the whole and to learn to act simply as one cog of the great military machine? Is there one who did not recognize the waste of life and treasure which follows the entering of a nation into war without proper preparation and prior training of her man power?

The author has given an interesting account of one item of the light railway work of the American forces in France. Before the United States entered into the war the necessity for light railways had been established as an essential part of the Army transportation system. Its zone of operations is from the rail-head beyond which the standard-gauge railways cannot be maintained, up to the firing line, a distance of about 10 miles ordinarily, although in the Toul Sector there was a regular service over a distance of from 26 to 33 miles. When hostilities ended 2 240 km. of light railways were under American Army control, of which about 300 had been originally constructed by the French, but rehabilitated by the Americans, 200 had been constructed outright by the American forces, and 1 740 had been captured from the Germans.

Up to February 1st, 1919, American-operated light railways hauled 860 600 tons of ammunition, forage, rations, water and construction materials and personnel, representing a ton mileage of 8 106 700, including the empty haulage.*

Though the material supplied, both track and rolling stock, proved satisfactory, there is need for further experiment and improvement. In

* Historical Report, Chief Engineer, A. E. F.

Mr. Black.

some respects the German locomotives were judged superior to those used by the American forces.

As a measure of economy in administration as well as to provide a means for trying out new devices in material and for giving training to a limited number of officers and enlisted men, the writer, when Chief of Engineers, advocated the installation of a system of light railways at each of the large permanent army camps. Such a system is installed at the Engineer Post at Camp A. A. Humphreys, Va., and its operation has resulted in a material saving of expense as compared with the usual transportation of men and supplies by motor trucks.

Mr. Wilgus.

WILLIAM J. WILGUS,* M. AM. SOC. C. E. (by letter).—The writer feels that it will not be amiss to touch on the early development of the Light Railway Section of the American Army's transportation activities in France. In June, 1917, as a member of a commission sent by the War Department to report on the railway needs of the armies of the Allies, the writer had an opportunity of cursorily observing the methods adopted by the British and French on the Western Front; and shortly after, when he was assigned to duty with Gen. Pershing's staff and undertook the task of planning for the transportation of American troops and supplies, he was able to use the information so gained as a basis for estimating the probable requirements in that respect, including "light railways".

In the absence of a decision as to the intended size of the American forces in France and where they were to fight, the writer arbitrarily assumed that within a year they would total 500 000 fighting men, equivalent to, say, 750 000 men in all branches of the service. Likewise, he assumed that the combat troops would function in the foothills of the Vosges, along a front of some 40 miles centering on Nancy, and that the volume of supplies of all kinds to be transported would average 60 lb. per man per day for all American forces, or 30 lb. per man per day in the advance area for those actively engaged at the front. It should be added that a 40-mile sector was assumed because it was understood that an average of 12 500 troops per mile of front was the maximum that could be effectively employed. Later, it was found that this average was too small and that the point of saturation was somewhere between 15 000 and 17 500 per mile.

A depth of from 5 to 12 miles along the front was taken as the zone within which supplies would be distributed largely by means of light railways, as experience had shown that it was unwise, from the standpoint of safety, to maintain standard-gauge rail-heads nearer than the lesser of these distances, while operating conditions forbade a distance in excess of the greater. The later experiences of the British led them to the conclusion that the light railways could function with

* New York City.

Mr. Wilgus.

the rail-head at a minimum distance of 8 miles from the front with nearly the same operating efficiency as at 5 miles, while the safety would be quadrupled. In fact, they considered, as a result of several years of trench warfare, that the depth of the zone to be served by light railways should vary from 8 to 16 miles, instead of 5 to 12 miles, the accepted practice at the time of our entry into the war.

Within this zone it was customary, in general, to have three single-track lines, parallel with the front, and connected with each other and with the standard-gauge rail-heads in such manner that the traffic of the group serving each rail-head would circulate in one direction over a multiplicity of routes, with ample insurance against serious interruption in case any part of the group should be injured by shell fire. The line nearest the enemy was intended for supplying the front-line trenches and light artillery, the second for the medium and the third or rear line for the heavy guns. The standard-gauge rail-heads, at which supplies and troops were transferred to the light railways, averaged a distance of 3 miles apart in the French sectors, each rail-head thus serving approximately 22.5 route miles or 30 single-track miles of light railways, which, in turn, distributed supplies for from 40 000 to 50 000 men.

On the basis of an average of 10 miles of single track, or 7.5 miles of route, per mile of front, it was estimated that materials should be ordered for 400 miles of single track, with steel ties (2 640 per mile), to which 20% was added for various services in the rear and for stock on hand, a total of 480 miles.

The requirements for turn-outs were found to average 10 per mile of single track, and therefore 4 800 sets were ordered, of which one-half each were to be right and left handed. It was designated that the leads should have a radius of 30 m. and that the ground switch-stands should throw parallel to the track.

As stated by the author, rails weighing approximately 20 lb. per yd. were in general use by the Allies, but there was a general feeling, especially among the British, that this was too light for the proper maintenance of track, ballasted as a rule with poor material and laid on soft ground often torn by shell fire. Under these circumstances a stiffer rail weighing 25 lb. per yd. was adopted, even though the heavier weight would be more disadvantageous in laying track. Lengths of rail were fixed at 5 m. with a small proportion of 2½ and 1¼-m. lengths for closures at curves; 20% of the rail was ordered curved, of which 70% was to have a radius of 30 m., 15% of 50 m., 7½% of 20 m., and 7½% of 100 m.

The question of ties was troublesome. The operations of the British lay in the flatter region of the North, where the soil was comparatively soft and where the topography was such as to require cuts

and fills; whereas with the French in the higher altitudes rock was at the surface and the terrain was such that tracks could be built on the contour lines with practically no grading. In consequence, the British in many places found necessary the use of such wood as they could pick up for interlacing between the steel ties, especially in shell-torn areas where it was necessary to raft the track over soft fillings. It was felt that the troubles of the British would be obviated by adopting short wooden ties, 4 by 6 in. by 4 ft., of which 115 000 were ordered specially for that purpose. Mr. Wilgus.

The type of fastenings called for careful consideration. The British did not look with favor on the French practice of riveting the ties to the rails because: (*a*) much trouble resulted from irregularity of the fixed gauge due to poor workmanship; (*b*) the rivets were said to rust and break under traffic, with resultant derailments; and (*c*) preassembling of the track parts prevented close packing for shipment and, in consequence, was wasteful of vessel and car space in transportation by sea and land. The latter reason, bearing as it did on the transportation factor that was to have so much to do with winning the war, was considered sufficiently forceful to dictate the use of clip fastenings which permitted the close packing of the rails and ties separately, and later their assembling when and where needed.

In the ordering of rolling stock the experience of the British was found to be borne out quite closely by an analysis of the requirements under the above-mentioned conditions.

Counting three gasoline locomotives as equal to one steam locomotive, the calculated needs, based on an average length of haul of 5½ miles, an average daily performance per equivalent working locomotive of 300 ton-miles and a surplus of 40% over actual working needs, were about 0.54 equivalent locomotives per mile of single track or a total of 258. Of these, approximately three-quarters, or 195, were to be steam locomotives. The remainder, multiplied by three, gave the required number of gasoline engines, 189, of which two-thirds were to have a capacity of 40 h.p. and one-third of 20 h.p. It was requested of the War Department that the steam locomotives weigh 3½ tons per axle and that the saddle tanks be hung so as to give a low center of gravity. The failure to observe this precaution with the British was the cause of frequent and embarrassing derailments on soft track.

As to cars, the British authorities gave their average requirements as ranging from 12 to 14 per route mile or 9 to 10½ per track-mile. Calculations based on the aforesaid data and on a daily performance of 27 ton-miles per working unit, and an allowance of 30% in excess of average working needs, yield a figure of 8.2 cars per route mile. Owing to uncertainty on this point at the time of estimating in July, 1917, a figure was used of approximately 9.3 cars per route mile or

Mr. Wilgus. 13 per equivalent locomotive, making the total number ordered 3 332, of the following types:

17-ft. bogie cars, open top, low sides	1 700
17-ft. bogie flats, with stanchions	480
8-ft. box cars	720
Bogie bolster	96
Tip cars	240
Bogie tank cars (1 500 gal. for army use)	96
	3 332

It was requested that the cars having a capacity of 9.3 long tons should have their contents capacity increased from 225 to 240 cu. ft., equivalent to the contents of the 10-ton standard gauge car of the European type, as practice had shown that this was highly desirable in transhipping ammunition at the rail-heads.

The cabled order, sent in July, 1917, also included 220 crossing-frogs of various angles, for intersecting standard-gauge and light-railway tracks; a selector telephone system for 330 miles of territory, with five dispatchers' outfits and station apparatus on the basis of stations one mile apart; 330 portable cabins; 48 portable gasoline pumps, including suction pipes and fixtures, each with a capacity of 3 000 gal. per hour against a head of 150 ft.; 48 000 lin. ft. of various sized pipe with valves and fittings; 48 demountable 15 000-gal. water tanks with valves and spouts; tools and machinery for a general repair shop and for 16 round-houses; maintenance tools for 420 track gangs; 20 locomotive cranes; a supply of 8 by 16-in. bridge stringers, and ample spare parts.

At that early date the question of forces for constructing, maintaining, and operating the light railway system was also considered. The experience of the British pointed to the following average needs per single track mile:

	Number of men.
Operation, exclusive of maintenance of way	10
Maintenance of way	14
Total	24
Construction (maximum)	20
Grand total	44

Therefore, it was contemplated that upward of 21 000 men would be required under these conditions.

In forecasting fuel consumption it was estimated that steam locomotives would require 48 lb. of coal per locomotive mile and gasoline locomotives 0.35 gal. per mile.

Mr. Wilgus.

The writer's connection with the "light railways" section of the Army's transportation service was terminated a few months after its inception, and hence he was not intimately in touch with its later development. He ventures the hope that the author will point out the faults of the original plan and procedure as here outlined, not only as an aid to those who later may have to cope with similar problems, but also as a warning against the inexcusable laxity and absence of ordinary foresight on the part of the War Department or other Governmental agency in having done absolutely nothing, prior to the entry of the United States into the war, to study the transportation needs and practices of the contending armies through experienced eyes, with a view to having in readiness a well thought-out plan embracing suitable provision for the material and personnel necessary for the prompt disembarking, storage, and distribution of American troops and supplies from the sea to the firing line.

It is also to be hoped that the author, in addition to pointing out the way in which possible errors in the early planning of the "light railways" may be avoided in future military operations, will also dwell on the extent to which the change from trench to open warfare modified the forecasts which were predicated on the preservation of the *status quo*. At the time of entry of the United States on the scene, the British considered that as far as any great advance was concerned, a forward movement of, for example, 5 to 8 miles in two days, would mean "open warfare", in which event the use of light railways would disappear; but it was of course unsafe not to order light railway materials on the theory that the Americans would be successful in immediately changing the character of operations. However, about the time the American Army commenced to function on a large scale, the enemy rapidly fell back on the entire Western front and this to a great extent relegated the light railways to the background. It will unquestionably be interesting and helpful to have known the extent to which this change in the military situation affected the usefulness of the means of distribution that had proven to be so indispensable while the armies were deadlocked.

Mr. Dunham.

H. F. DUNHAM,* M. AM. SOC. C. E.—The speaker wishes this paper had been extended to include facts relating to the traffic and operation of trains on so narrow a gauge. The author when concluding the discussion may mention difficulties that do not pertain to transportation on standard gauge lines.

Col. James B. Dillard, U. S. A., read a paper before the American Society of Mechanical Engineers, on December 5th, 1918, from which the following paragraph is quoted:

"The 1918-model, 8-in. gun, railway mount which uses the same barbette carriage as the 7-in. gun may be elevated from 0 to 42 degrees.

* New York City.

Mr. Dunham. It fires either a 200 or 300-lb. projectile at a maximum velocity of 2 000 ft. per sec. and has a maximum range of about 69 000 ft. By means of special 8-wheel trucks it is possible to transport this mount over a 60-cm. (24-in.) narrow-gauge track. This 8-in. mount weighs about 180 000 lb. and it certainly is a great advantage to be able to transfer it to a narrow-gauge track which is the kind used at the battle-front in order to better conceal operations. On the narrow-gauge track a speed up to 15 miles per hour is feasible. The Ordnance Department which developed this mount in its entirety considers this artillery piece to be the last word in railway mounts. It is also the only mount of its kind in existence."

Any further description of such unexpected loading and service would be especially interesting.

There are now many miles of 2-ft. gauge railroad in use in the United States, not as logging or factory-yard roads, but as veritable railroads serving many communities and functioning in all respects like a standard gauge steam road except that freight, passenger, and drawing-room cars are not exchanged, but always remain on their own tracks. Cars are not lost and a company can do its own repairing.

The Bridgeton and Saco River Railroad,* more than 20 miles in length, is a narrow-gauge (2-ft.) road of this type, which connects Bridgeton Junction on the Maine Central Railroad with Bridgeton and Harrison, Me. The alignment includes one 36° curve, one 20° curve, and others of longer radius. The grades reach a maximum of 4% for short distances. The road operates 5 locomotives, 6 freight and passenger cars, and a total of 72 cars. The locomotives weigh from 22 to 36 tons each. These engines have two driving axles about 54 in. apart, a one-axle pony truck and tender on the engine frame extended. The freight cars are more than 33 ft. in length, 6 ft. wide and 6 ft. high in the clear, weighing 7½ tons, and carry a net load of 15 tons. The noticeable difference in the passenger car is the "one-seat" feature on each side of the central aisle. The average speed is more than 20 miles per hour.

This road was built prior to 1888 and for many years before the World-War disturbance and high prices, it had paid regular dividends. In 1915 it carried 34 500 passengers and 31 500 tons of freight. These figures, however, do not show the great value of the road to those residents who without it would be shut off from the outside world for long periods. Its trains are said to be always waiting for the Maine Central trains in the intervals of trouble from deep snows; in fact, the narrow gauge is said to be an advantage in heavy drifts.

From Farmington, Me., in a northerly direction, the Sandy River and Rangeley Lakes Railroad of 2-ft. gauge has now 106 miles of similar roadbed and track and 16 miles of sidings. This road operates 14

* The speaker illustrated his remarks by a moving picture film showing locomotives, cars, and roadbed of this railroad.

locomotives, 18 passenger cars, and a total of over 300 cars, and the revenues from operation in 1918 were $234 955. The weight of rail varies from 25 to 58 lb. per yd. Mr. Dunham.

A traveler on these narrow-gauge roads is LOT subjected to hardship, and records do not indicate added risks. Extra fare insures a seat in the drawing-room or chair car and the principal difference in the passenger's sensations is a feeling that the ground is not far away. The low center of gravity makes for safety. When cheaper motive power, for example, hydro-electric and storage battery service, can be provided, such 2-ft. gauge lines should become more numerous where there is not business enough to justify standard gauge construction.

MORRIS E. PUMPHREY,* ESQ.—The speaker was with the 21st Engineers at Sorcy, Meuse, which place has been described by the author, from March to October, 1918. Afterward, he was in the Argonne, and it is thought that a few details of his experiences may be of interest. Mr. Pumphrey.

One of his first duties on arrival at the front was to make a reconnaissance for the purpose of connecting the light railway lines in the St. Mihiel Sector with the German lines, in case of advance. This plan was properly studied and prior to the St. Mihiel advance, large quantities of light railway material were brought up adjacent to the front-line trenches. On the morning of September 12th, 1918, preparations had been completed for the laying of the tracks across "No Man's Land", as soon as the infantry had advanced.

The speaker was located at a town called Flirey, about 400 yd. from the front-line trenches, where he had one company of experienced light railway troops, with one company of negro labor troops, which had just arrived in France and had had no experience with construction work. These were the only troops available for this work and were totally insufficient in number. On the morning of September 12th, the infantry went over the top about 5 o'clock and the engineering troops immediately started to construct the light railway across "No Man's Land". As the infantry advanced, a party of experienced engineers laid out the line on the ground and marked it with the white trench tape. As may be imagined, this line was very uneven and lacked a great deal in the way of uniform grades and curves. At this point 4 km. of track had to be built. Due to the shortage of labor and lack of ballast, it required 4 days to get this line in operation, whereas it should have been built in 12 hours in order to have been of real use to the combatant troops.

After this line was completed, the regiment to which the speaker was assigned was moved to the Argonne Sector, where no light railway troops had been available before. The Argonne advance began on September 26th, 1918, but it was almost the middle of October before

* New York City.

Mr. Pumphrey.

any definite headway had been made in connecting the American light railways with the German lines. This was due to an insufficient number of troops, lack of material, and a great lack of proper planning before this operation was put into effect. By November 1st, the light railways in this sector had been well connected up and traffic was operating smoothly. As the combatant troops advanced November 1st, for the final phase of the Argonne battle, more light railway troops and material had been made available, so that for a few days it was possible to maintain connections with the advancing infantry, but by November 11th, the infantry had advanced so far that the line of supplies had almost collapsed. On November 11th, supplies were being hauled on one line for a distance of 55 km. and on another for a distance of 60 km. Both these lines were handling approximately 1 000 tons per day of rations and ammunition.

The locomotives which were furnished for light railway work proved to be very unsatisfactory, the steam locomotive being top-heavy. The speaker recalls the case of one Captain in the regiment, who re-railed 65 of these locomotives in 1 month, which would seem to be a record. The gasoline tractors worked very well at times, but generally failed at the crucial moment.

It was found that curves with a radius of 50 m. are as sharp as should be used and that no grades exceeding 3% should be considered. Recently, in one of the engineering papers, some writer has suggested the advisability of adopting wooden ties, instead of steel ties for sectional track such as was used by the Armies engaged at the front. It was quite right to use the wooden ties on back lines where there was ample time for the construction of first-class track, but it certainly would not be advisable to use wooden ties near the front, on account of the delay in transporting them.

The speaker is firmly of the opinion that the 20-lb. rail used by the English is the ideal rail for the 60-cm. railways. However, it is understood that the engineers of the War Department are recommending a 25-lb. rail.

During the early part of 1918 the speaker made a detailed study of the French light railway system from St. Mihiel to St. Die in the Vosges Mountains and found that sharp curvature and heavy grades were common on the French railways, that the road-bed as a rule was too narrow, and that insufficient ballast was provided to make a good track, although in numerous cases masonry retaining walls and culverts which would be a credit to the standard railways in the United States were found. This work, as can readily be imagined, was absolutely unnecessary in war-time construction.

Mr. Hoyt.

HAZEN L. HOYT, JR.,* ESQ.—If the American people are to derive any benefits from the World War, it must be by profiting by the

* New York City.

lessons learned both at home and abroad. It is necessary, therefore, that the good and bad points of the different services and departments be carefully weighed before drawing conclusions, and this is true of the light railways of the battle fronts in France. Mr. Hoyt.

The author has given a clear idea of the types of equipment used abroad and of the work done by the light railways in France, but he has failed to bring out wherein they failed in their functions.

At the outbreak of the war many kilometers of military railways existed in France, principally in and around the permanent fortifications of that country, and it is, therefore, only natural that when the fighting settled down to what was known as a "warfare of position" that these railways should be extended to help supply the troops in the line, especially as motor-truck transportation has never been developed abroad to the extent that it has in the United States. However, the Allies soon realized the need of this form of transportation, and large orders were placed both at home and abroad to supply this demand.

When the United States entered the war these 60-cm. railway lines were well established, and portions of them were taken over by the Americans with the sectors assigned to them. The railway locomotives used by the Americans in France were manufactured by the Baldwin Locomotive Works, as stated by the author, but, in the speaker's opinion, proved to be absolutely unsuited to the service they were called on to perform. The steam locomotives were entirely too high, had insufficient steam capacity, and were badly adapted to the kind of coal they had to use. The spring suspension was poor and only 68% of the weight of the locomotives was carried on the drivers. The over-all length was too great in proportion to the rigid wheel base, causing the rear drivers to pull off the rails when hauling heavy trains around sharp curves. Although these locomotives were designed to negotiate 30-m. curves, it was found that 40-m. curves had to be adopted as the minimum and curves of 50 m. were used where possible. Why this type of locomotive should have been adopted, the speaker is at a loss to understand, as double-truck steam locomotives had been manufactured in this country for the Allied Governments prior to the entry into the war by the United States and had proved entirely satisfactory. So poor was the ability of these locomotives to stay on the track, that one company of the 21st Engineers operating and maintaining approximately 50 km. of track during the Argonne Drive had to re-rail 65 locomotives in 1 month.

The gasoline locomotives worked better as far as their ability to stay on the track was concerned, but the standard of workmanship and material was low, and mechanical troubles were constantly arising, principally with the clutch and gear case. The spring suspension also was poor which, combined with the large overhung weight

Mr. Hoyt.

at either end, caused a jumping effect at high speed, frequently resulting in derailment.

The cars were far too heavy for their load capacity and trouble was constantly being experienced with the draw-bars, due largely to the great amount of side play allowed, resulting in frequent instances of broken draw-bars when coupling up the trains. If a four-wheel car of half the capacity had been adopted, the weight could have been reduced by nearly two-thirds, besides such cars would have been far easier to re-rail than the eight-wheel double-truck type furnished.

The author states that both the English and French Armies had found that it took approximately 21 000 man-hours to build 1 mile of 60-cm. track. In this connection, it would be well to give some figures of the work done by the 11th Engineers during the Cambrai Drive in November, 1917. Working in conjunction with about 350 men of the 4th Battalion of Canadian Railway Engineers, 300 men of the 11th Engineers laid approximately 10 miles of standard-gauge track in 7½ days, from Epehy to Marcoign. The best time was made by the Americans, who laid 1¼ miles of track in 5 hours and 46 min. This work consisted in re-laying the rails and ties, filling in shell holes, mine craters, blown-out culverts, trenches, etc., the ballast being already in place as the line followed along the old right of way of the Nord Railroad, running from Peronne to Cambrai.

Another matter which caused endless trouble for the troops operating the light railways, was the voluminous reports required by the Department of Light Railways, many of which it was impossible to supply and almost all of which could not be given accurately, due to the conditions of operation. This was particularly true of the reports on coal and gasoline consumed, as much of this material was obtained from captured German dumps and the quantity could only be approximated, as no weighing apparatus was available.

Another source of annoyance was the difficulty, if not impossibility, of securing permission to change the equipment in any way, as this meant a change in the standards. Many of these changes were minor, but would have helped materially in the operation of the trains and could have been done easily by the troops themselves had permission been granted.

As stated by the author, the main shops of the light railways were located at Abainville, almost directly back of the center of the Toul Sector; this town also was the supply base for the light railways. Until the lines started to advance it served its purpose very well, or would have, had the shops been completed. After the First Army moved to the Argonne, however, this base was about 70 to 80 km. away by road and nearly twice that distance by rail, requiring nearly three days' travel by rail and almost a day by road in order to obtain supplies. Even when these supplies arrived at the light railway shops of the First Army, at

Dombasle (in Argonne), they were nearly 60 km. from the advanced railway companies. Mr. Hoyt.

These were the conditions existing at the time of the advance of the American troops in the Argonne, and previously on a lesser scale in the St. Mihiel Salient. The first proposition that confronted the Americans, of course, was to throw a line across "No Man's Land" in order to connect up with the abandoned German track. Prior to the opening of the St. Mihiel offensive a careful study had been made of the situation, and material of all sorts had been provided for connecting up the German lines at three points: From Flirey to Essey, from Bois Chenau to Woinville, and from Point au Metz to St. Baussant, the average distance being about five miles, including the approaches on both sides and the distance across "No Man's Land". Work was started simultaneously on all three lines on the morning of September 12th, 1918, but it was not until about October 1st that these lines were fit for train operation, in spite of ample troops and material having been provided beforehand.

This same condition existed in the Argonne, aggravated by a marked shortage of rails, ties, etc., as time and transportation had not been available for their concentration back of the lines. So great had been this delay that at the time the Armistice was signed the farthest point of light railway operation was about Buzancy, or approximately half way from Varennes to Sedan. Furthermore, this point marked about the end of the system of German light railway track abandoned by them in their retreat, and from here the Americans would have been compelled to build entirely new lines to supply the troops if the forces had been pushed ahead. This condition existed in spite of the fact that somewhat more than 6 000 men were employed on the light railways of the First Army at that time.

From this it can be readily seen that, although the light railways had proven their value in a "war of position", they proved totally inadequate in following up an extended advance, and the troops were forced to fall back on the road transportation for their supplies.

Reviewing the conditions as they existed on the St. Mihiel and Argonne fronts during the advance of the American forces in September, October, and November, 1918, it is the speaker's opinion that better results would have been obtained if every effort had been centered on pushing forward the standard-gauge rail-heads, which at the time of the Armistice had reached Varennes, and improving the roads, so that the greatest possible volume of road transportation could have been used for the supply of the troops. This would have necessitated a careful study of the available roads and a well-trained body of Military Police to handle the traffic and avoid congestion. In order that these roads might be kept in the best possible shape, the men and ballast used on the light railways should have been diverted for this

Mr. Hoyt. purpose, leaving the 60-cm. lines to handle the salvage collected from the battlefields, pushing forward their lines as conditions permitted.

Mr. Poland. W. B. POLAND,* M. AM. SOC. C. E.—Illustrating the critical situation as to transportation at the front: In the early months of 1918 the speaker attended a conference between representatives of the American Expeditionary Forces and the British Army Transport Service, represented by Gen. Thornton, formerly of the Long Island Railroad, then in charge of transportation along the British front.

After explaining the terrible straits of the Allies, for cars and locomotives, Gen. Thornton said: "If the line stays where it is, we can probably get up our supplies and ammunition, but if the Boche ever retreats, God help us, we're lost!"

Mr. Pugh. MARSHALL R. PUGH,† M. AM. SOC. C. E. (by letter).—The author has touched but briefly on a phase of light railway work about which he is well qualified to speak, namely, the light railways in the extreme forward areas, where conditions differed materially from those obtaining farther away from the trenches.

The light railways as operated by the American Expeditionary Forces may be divided into three zones:

(*a*) Near the rail-head, operated by steam locomotives.

(*b*) The forward area, operated by gasoline locomotives.

(*c*) Tram lines at the extreme front, using animal or man power.

Wherever the lines were far enough from the enemy to be reasonably safe from shelling, steam locomotives were used, as they were more powerful and could haul heavier trains. The gauge of track was 1 ft. 11§ in., and the over-all width of the steam locomotives was 6 ft. 5 in., consequently they needed a substantial track. Nearer the front, the light at night and the steam and smoke by day made them undesirable, so gasoline locomotives were used. Where their use was impracticable even at night, as well as on numerous spurs to batteries, mules and horses were used, or the ammunition and supplies were transferred to light cars pushed by men. Fig. 10 shows a light car transporting water on a spur reaching within a few yards of the front-line trenches, and is typical of tram-line conditions at the extreme front.

The first, or (*a*) zone, approximates more nearly to an ordinary railroad, and has wooden ties, rock or gravel ballast, and comparatively light grades and curvature. The road is divided into blocks with a telephone train-despatching system. Where not subject to shelling, small huts were used by the despatchers, as shown in Fig. 11. These huts were made in sections hooked together and could be taken down in a few minutes, moved, and re-erected at another place with equal rapidity.

* New York City.

† Wayne, Pa.

Fig. 11.—Portable Despatcher's Hut, La Reine.

Fig. 12.—Despatcher's Hut, Broussey, Showing Sand-bag Protection.

Fig. 13.—Camouflage at the Front.

Mr. Pugh.

In the forward zone semi-circular steel elephant huts were used to house the despatchers. These huts were protected by sand-bags as shown in Fig. 12, which is a view of the despatcher's hut in Broussey. This hut was at the terminus of the gasoline-operated section, beyond which animal traction was used. All operation was by night, and the curtain screen hung across the roadway was to hide it from enemy observation.

The road in exposed places was screened by camouflage, as shown in Fig. 13. At first, there was a great deal of hesitancy about building much in the open in forward areas, but experience showed that it is very difficult to hit such a narrow target unless it is directly enfiladed. Near Beaumont, a point called "Dead Man's Curve" was subjected to shelling for months, but comparatively infrequent repairs to the track were necessary. When a shell did hit the track, it was a simple matter to take out the damaged section, or sections, as shown in Fig. 14, and replace them by new sections. Wrecking trains were stationed at intervals, on which were carried some full length (5-m.) sections of track and some half and quarter sections, ready to make a quick run to any damaged point and replace the track. The difficulty of hitting the track and the ease of repair makes it far more costly to destroy a light railway by shell fire than to restore it. It is about as impracticable to destroy such a railway by shell fire as it is to get rid of cooties in the same manner. This fact is their protection.

There were two abandoned meter-gauge railways in the Toul Sector, and in places much work and ballast was saved by laying the light railway track in the center of the old meter gauge, as shown in Fig. 15. The dug-outs and huts shown are in the shelter of the old railroad cut just behind the trenches and are occupied by the troops holding that part of the line. As illustrating the amenities of life in this region, one of the writer's corps making a railroad location in "Shrapnel Valley" just to the right of this point, was hailed one day by an officer who said that the Boche had broken through and he wanted the survey party to help man the machine guns till reinforcements arrived. The survey was temporarily deferred.

Just south of this point the light railway left the meter gauge, which formerly crossed on the bridge shown in Fig. 16. Barbed wire entanglements are shown in the foreground, also one of the narrow-gauge "speeders". These little speeders were used by officers and men, repair gangs, and the like, for getting over the road, and were indispensable. Their usefulness would have been far greater, however, had they been adapted to the service they were called on to perform. There were two types. The one shown in Fig. 16 held six persons; it had one cylinder, was cranked by pushing it along the track and, when on a heavy grade, good track was absolutely essential, as it would stall if not moving rapidly. The smaller speeder, holding three persons, had two cylinders, was swifter and more easy riding, but stalled even more

Mr. Pugh. readily on grades and jumped the track on no provocation whatever. The writer preferred it to the other, but took many an unpleasant spill. Derailments were constant with each type, as they had no clutches, and although they would run well on a smooth track, they could not be operated slowly and were entirely unsuitable for conditions at the front. Several serious injuries and one death occurred from their use by the 21st Engineers. They should have had clutches, means of cranking, and have been geared so that they could run slowly on poor track. There is a good, light friction-drive speeder in the market.

The general instructions on location were to avoid heavy work, and Figs. 11, 13, 14, and 18 indicate the character of the great bulk of the line constructed. Where the track leaves the rail-head at Sorcy Yard, on the curve marked "To Cornieville" on Plate XXVII, there was a ridge to be crossed, and as heavy traffic had to be handled, the writer put in the only heavy work in the line—a 17-ft. rock cut shown in Fig. 17. A French highway is carried by the bridge in the foreground. There was considerable criticism prior to the completion of this cut, but the writer heard of none after it was finished and operation showed the justification for it. In general, however, work of this character would be utterly misplaced in light railway lines. Ease and speed of construction are generally of paramount importance, and it is also necessary to know just how long it will take to construct a given line under prescribed conditions as to number of men available. The construction forces must be divided in such a manner that grading, track-laying, and ballasting will progress with equal rapidity, so that the line will be completed without any delay due to the track being held back by grading, or by ballast not keeping up with the track. Conditions varied materially, but a rough average of the lines in the forward part of the Toul-St. Mihiel Sector indicated that with approximately a 1-ft. cut or fill, the forces should be proportioned as follows:

Clearing	5	men.
Grading	60	"
Track-laying	10	"
Ballasting	25	"

Progress charts were prepared, and when the work was completed, it was checked against the preliminary estimates, as shown in Table 2.

The Sorcy-Cornieville Line aggregated 2 344 man-days per mile, comparing in this respect with the Abainville Line cited by Col. Jonah. Each was what may be termed a trunk line. The Hamonville and Raulecourt Lines, on the contrary, were close to the front, with light grading and sectional track. The Hamonville Line averaged 1 024 man-days per mile and the Raulecourt Line 1 169 man-days per mile. The Abainville Line and the southern part of the Cornieville Line were laid with wooden ties. At the Cornieville end steel ties and sectional track

FIG. 14.—REPLACING TRACK DAMAGED BY SHELL FIRE.

FIG. 17.—EXCEPTIONAL WORK ON LIGHT RAILWAY; 17-FT. ROCK CUT AT SORCY.

Mr. Pugh.

were used, which afterward were replaced by wood. To avoid interruption to traffic during the change, the wooden ties were placed between the steel ones, and the new rail, bolted together in sections several hundred feet long, was laid on either side of the sectional rail. After the passage of a train the sectional track was lifted out, thrown to one side, and the new rail quickly spiked to the wooden ties, only four bolted connections being necessary for the entire section. Fig. 18 shows this operation. The new rail is ready to be spiked into place as soon as the sectional track is lifted. In the foreground enough of the 25-lb. American rail on wooden ties is shown to indicate its superior alignment and solidity.

TABLE 2.—ESTIMATED AND ACTUAL PERCENTAGES OF WORK ON "K" LINE (RAULECOURT).

	Estimated percentage.	Man-days.	Actual percentage.
Clearing	4	69	5.11
Grading	60	751	55.59
Track-laying	10	199	14.73
Ballasting	26	332	24.50

It will be noted that the lines at the extreme front averaged only about half as many man-days per mile for construction as those farther back. They had few bridges and all the work was light. On the contrary, given an equal amount of traffic, the maintenance on these lines was greater, and wooden ties held up much better than steel ties.

What lesson experience in the World War teaches as to the defects that developed in the light railways, and the remedy, is a question of utmost importance.

Paul McGeehan, M. Am. Soc. C. E., in an article entitled "Notes on Army's Light-Railway Practice in France",* has put his finger on what the writer considers the lesson to be profited by if light railways are to be made the success which their importance demands. Capt. McGeehan says, "The number of derailments was almost a scandal. On one classic occasion at Tincourt, on the British front, all of the steam locomotives in the service were on the ground at the same time. Derailments were so numerous and the cause of so much loss of time that orders had to be issued to reduce speed to not more than eight miles an hour."

The first and most obvious part to which consideration should be given is the roadbed. Ballast is by all odds the most serious problem in light railway construction. In Table 2 it will be noted that 24½% of the labor, on that particular branch, was used on ballasting, but this does not begin to cover what is involved in that part of the construction.

* *Engineering News-Record*, October 2d, 1919.

Mr. Pugh. The quantity of ballast needed and the long hauls frequently necessary before it can be placed, choke the railroad with ballast trains. In the week ending April 19th, 1918, of 4 674 tons hauled on the light railway, 1 290 tons consisted of ballast. For the week ending August 31st, 1918, the total hauled was 19 885 tons, of which 2 717 tons were ballast. The following week the figures were 34 942 tons total, 7 954 tons of which were ballast. In general, the ballast varied between one-tenth and one-quarter of the tonnage moved. Capt. McGeehan calls attention to one instance where ballast had to be fed continuously into certain lines in order to keep ration trains running. "Ballast, even, had to be put under this track to keep the ballast trains themselves running." He agrees with Col. Jonah in considering wooden ties preferable, because surface and line are more readily kept, and steel ties cut into the ballast. Their contention is not open to dispute, and when it can be done the writer would advocate their utilization, but he feels that in the forward areas the superior speed with which sectional track can be laid, especially at night, the lessened demand for skilled labor, and the avoidance of noise due to spiking, make the bolted sections with steel ties vastly preferable.

Much of the sectional track used by the American forces was French Decauville track with 16-lb. rails. This is too light for main track, and the head of the rail is too narrow to give the drivers proper adhesion. The American 20-lb. and 25-lb. rails were superior in every way. Personally, the writer prefers the 20-lb. rail, as it seemed to be quite as satisfactory and is lighter to handle. It is a mistake to have both. The difference in appearance between the 20-lb. and 25-lb. sections is negligible, and in one instance led to disastrous results. A start was made to lay several miles of sectional track, and after quite a stretch was down, the sections failed to fit. It was then discovered that the erection shop had forwarded to the front sections having one 20-lb. and one 25-lb. rail to each section. It was not noticed as long as the sections happened to have all the 25-lb. rail on the same side. When, however, a 20-lb. rail came to match up against a 25-lb. rail, trouble began, and a gentle critique of the erection shop by the track-layers ensued.

The American standard sectional track, 5 m. (16 ft. 5 in.) long, had eight ties, with a total tie area in bearing of 13.76 sq. ft. per section. The German sections were not all alike, but in general had ten ties to the section. One excellent type had a total bearing area of 23.2 sq. ft., or 176% of the area of the American section. The American 20-lb. rail section weighs 406.4 lb. The German section with American 20-lb. rail would weigh 549 lb. Although heavier to handle, it would not be objectionable. Furthermore, the German ties are 4 ft. long, 5 in. longer than American ties, giving somewhat superior stability. Of most importance, however, is their width which is 7 in. as against 5½ in. for

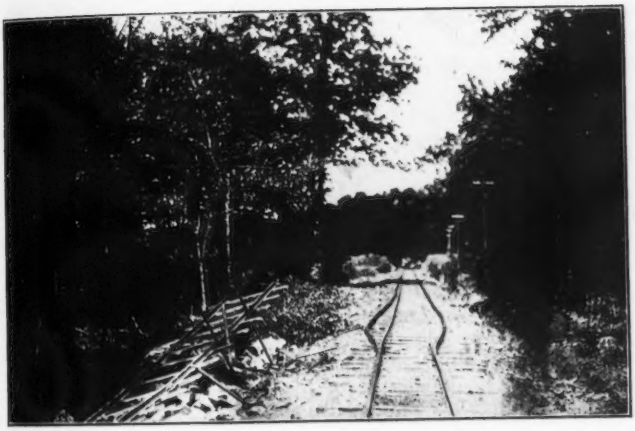

FIG. 18.—REPLACING SECTIONAL TRACK BY RAIL WITH WOODEN TIES.

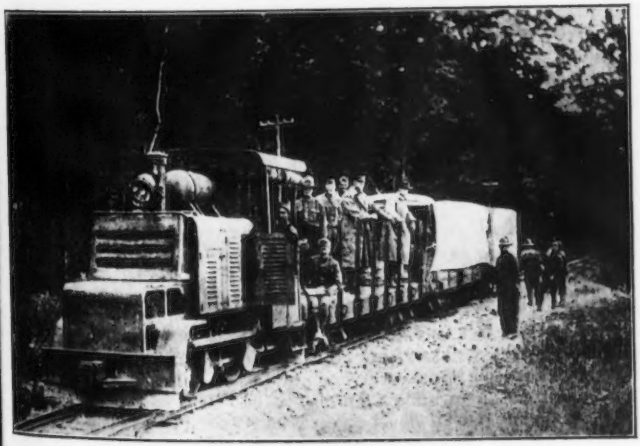

FIG. 19.—LIGHT RAILWAY GASOLINE TRACTOR AND FLAT CARS.

American ties. The Second Progress Report* of the Special Committee to Report on Stresses in Railroad Track throws an interesting light on the relative supporting capacities of these two widths of tie. It shows that the supporting capacity is greatly increased by increase of width. Table 18 of that report indicates that "with jarring" the German tie would support a load of approximately 160% of that of the American tie. Since there are 25% more ties to a section, the superiority of the German section on a poor soil is apparent. Mr. Pugh.

The writer would advocate the continued use of sectional track at the extreme front, or wherever speed in construction is essential, using on soft ground a mat of brush, leaves, or the like, when obtainable, before placing the ballast. Where wood is available, he has found great benefit to result from inserting between the steel ties on bad ground either wooden ties, planks, or boughs of trees, to give added bearing power and stability.

As to gauge, where an enemy's lines have the 60-cm. gauge, as was the case in France, it is undoubtedly preferable to adopt the same, so that his lines may be utilized in an advance. Otherwise a 30-in. gauge would be preferable. Neither the rolling stock nor the track would weigh any more, and the tendency to derailment would be less.

Practically all the articles which the writer has read on the subject regard the great part of the troubles in light railways as arising from poor roadbed. Desirable as some track changes may be, they are of minor importance, in the writer's judgment. It must be borne in mind that under battle conditions the roadbed must and will be poor. It is vitally necessary to get cars and engines that will run on a poor roadbed. This has been the writer's contention from the start. American rolling stock was based on the idea of a miniature standard-gauge railway. It should be based on that of a contractor's rough-and-ready construction railway. An interesting side light is thrown on this by a remark on page 218 of the "Historical Report of the Chief Engineer * * * American Expeditionary Forces," where it is stated: "It was found that the lines of the German system contained many sharp curves and heavy grades, which called for reduction before American equipment could be successfully operated." Lieut. Harvey W. Bell, of New York City, formerly of the 21st Engineers, A. E. F., a mechanical engineer of great experience in industrial railways prior to the war, as well as in operation of light railways in France, writes:

"I took six trains of about seven cars each, using steam power, from Sorcy to the Argonne. We passed near Mt. Sec and ran near the new front over German track and had some pretty exciting times. Our locomotives made so much noise and showed so much light that they must have been easily located. To add to our troubles both engines and cars seemed always to leave the track as soon as shells began to land near us.

* *Proceedings*, Am. Soc. C. E., February, 1920, p. 133.

Mr. Pugh. One night in the Argonne our steam engine turned over on its side on a bad curve, blocking the main line. We worked until midnight getting it up again, and no sooner were we prepared to start than it turned over on its other side and we didn't get it up till morning. I could tell you a hundred stories of a similar nature with our equipment, yet I never saw a French engine or gasoline locomotive off the rail."

The American gondola and flat cars were 24 ft. 1¼ in. long over couplers, and 15 ft. center to center of trucks. The weight of the gondola was 9 000 lb. and of the flat car 8 000 lb. Lieut. Otis T. Gregg, of the 21st Engineers, also a man of wide experience in industrial railways, suggests a four-wheel car which could be made of one-half the capacity and one-third the weight and which six men could lift on the track. The little four-wheel, V, dump cars, 6 ft. 9 in. long over couplers, kept the rails on rough track and would go around curves which the other cars would not begin to take. Fig. 21 shows how heavy loads can be moved by very simple rolling stock.

The steam locomotives (Fig. 11) were too high, had a bad spring suspension, and only 68% of the weight of the locomotives was carried on the drivers. The rear drivers would pull off the rail on the inside of the curve when hauling a heavy train over sharp curves, because the over-all length was too great in proportion to the wheel base.

In locations fixed by the 21st Engineers compensation for curvature on grades was made at the rate of 0.02% per degree of curve. Nevertheless, with the long cars operated by the Americans, curves offered much greater resistance to traffic than grades.

The writer's regiment was fortunate in having several mechanical experts of great ability, and they were in entire agreement with him—he is not a mechanical engineer—as to the desirability of a different type of rolling stock. Lieut. Alfred D. Chandler, Jr., now representative of the Baldwin Locomotive Works in South America, was most insistent on the need for a revision in the design of American engines. A double-truck gasoline locomotive with all the weight on the drivers, a motor of about 75 h. p., and a four-speed transmission, to replace both the steam and the gasoline locomotives would be, in the opinion of those better qualified than the writer to pass judgment, a great change for the better. In France, conditions occurred in which the locomotives had to remain miles away from proper supplies of coal and water and pit tracks. Gasoline locomotives could carry supplies of all kinds sufficient for four days' hard work.

In stressing the question of rolling stock, it is possible that the writer's meaning may be misconstrued. It is not his intention to advocate poor track. Make it the best that is possible, but when conditions compel that "best" to be poor, have cars and engines which will run on the worst of it, and which can readily be re-railed.

Fig. 20.—Flat Car Loaded with Ammunition.

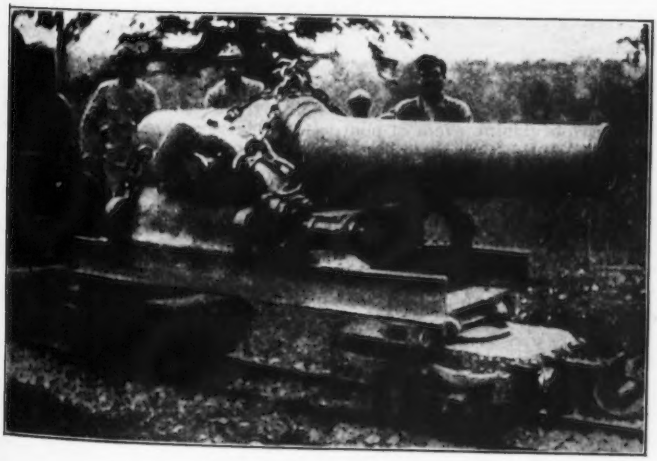

Fig. 21.—Howitzer on the Light Railway.

Mr. Pugh.

The light railway is not adapted and should not be used for long hauls, which can be far better taken care of by the standard gauge. It is not practicable to destroy it by shell fire, so that it should be used where the standard gauge cannot be operated, with necessary extensions to the rear to reach properly located shops and to enable the withdrawal of equipment in event of an enemy advance, these extensions to be located and built in accordance with the best principles of standard-gauge practice.

On page 1221, Col. Jonah has clearly and succinctly stated the primary reasons for the development of light railways. Some concrete examples of what the light railway does may be of interest. Maj. G. Boyer, of the 4th Canadian Division, in a report to Sir Henry Jacob, gives an idea of the great saving in work effected by them. He says:

"Before the tram lines were organized and constructed one horse and one man brought to his battery eight 18-lb. shells, therefore to deliver 16 000 rounds it took 2 000 horses and 2 000 men; by the tram lines, taking as an average a hundred rounds per truck, it would take 160 horses or mules and 184 men; saving and allowing to rest 1 816 men and 1 840 horses or mules."

Light railways are also of the greatest aid in troop movements, saving tiresome marches (generally at night) and relieving the already congested highways. An extract from a citation to the 21st Engineers by the Commanding General of the 82d Division illustrates this point very clearly. He says, in part:

"The light railway is a great saving on trucks and gasoline; also a great saving on the men, who were saved physical exertion moving about and were able to apply the exertion in other more important work. It also made it possible for the men to move quickly during the reliefs, where to camp men in unusual stations or move them about in daylight would attract enemy fire and suspicion. Some 20 000 troops were moved in a recent relief, much to the benefit of the troops."

The writer would like to take this opportunity of expressing his appreciation of the great help which the author's keen observation and trained judgment was to him on the location and construction of the light railways. He is deeply indebted to Col. Jonah for his criticisms and suggestions.

Mr. Perry.

FRANCIS W. PERRY,* ASSOC. M. AM. SOC. C. E.—The speaker's service with the American Expeditionary Forces in France was first as Quartermaster, then as Deputy Chief of Staff of a combat division (77th Division), and, finally, as a member of the General Staff of the First Army. The division was attached to the British Expeditionary Forces in April, after the opening phase of the 1918 German offensive, on the right of the British front, in Picardy, and during the second phase, on the left, where the offensive was directed toward Hazebrouck,

* Brooklyn, N. Y.

Mr. Perry. in the Hazebrouck area. During the third phase (on the left of the French front, toward Paris) the battalions of one infantry brigade (the 154th) were put in the line on the new Picardy front. Then the division was moved to the Lorraine front, where it was brigaded with the French, at Baccarat. The headquarters of the First American Army were formed near Chateau Thierry, at La Ferte-sous-Jouarre, in July, 1918, and the speaker joined in the same month, serving in turn as Secretary of G-3 (Operations) and as Chief of Sub-Section, through the "Second Battle of the Marne" and through the preparations for the reduction of the St. Mihiel salient.

Two types of narrow-gauge field railways were in actual use on the different fronts. The French used both the 60-cm. and 40-cm. gauge track, but the difference between the two types was one of character rather than gauge. The British distinguished them by calling one type "light railways" and the other "tramways".

The French staff maps show the many meter-gauge railways of Belgium and France as "tramways". There will be no confusion of terms when it is remembered that these tramways are privately owned roads and the narrow-gauge field railways under discussion are purely combat railways.

The so-called tramways were the field railways of the forward areas, beyond reach by other railways. They were built of track of the portable type. Tram locations were made with more cunning, in woods, folds of the ground, or in trenches, and with less regard to limits of grade or curve, than were necessary for the light railways. They were operated by light tractor, gravity, horse or mule, or man power.

As a result of experience with movements of the battle line, there was a tendency to build the main forward tram lines of 60-cm. gauge tracks and of the same weight of rail as that used for the light railway, and to locate them with a view to pushing them forward, following an advance, and then developing them as light railway lines of connection with the enemy systems of field railways. The ordinary function of these tramways was to supplement the regimental horsed transport, and pack mules and carrying parties in the trench areas.

The British had used a 9-lb. tram rail, but afterward this lighter weight rail was reserved for short lines, as between artillery dumps and battery positions. It was not necessary that the tramways, as lines of supply distribution in the trench areas, should take off from the light railways; they were as useful from the railway or road dumps.

Referring to the map (Plate XXVI), the standard-gauge railway—Conflans-Baroncourt-Longuyon-Montmedy—circling the Briey iron district, was the main supply line of the Army of the West. This line was a highly improved, double-tracked road paralleling the front from

Switzerland to the North Sea—a *voie-de-rocade*. In general, the narrow-gauge field railways were located in the zone between the main supply line and the battle line, on all the fronts. Mr. Perry.

Viewing the front from the German side, the strong Verdun salient threatened the main supply line. The Germans had one other way around, namely, the standard-gauge railway north by way of Thionville to Luxembourg, where connection was made with the Coblenz-Luxembourg-Namur-Brussels line. These supply lines were cross-connected, notably at Longuyon, an important junction with many long sidings.

The German right on the Verdun salient was the American Meuse-Argonne front. Here, the field railways appear as typical area systems. That on the extreme right was located in and about the Argonne Forest. At the close of the war, the German light railways had reached a depth of about 20 miles from the organized front. They paralleled standard-gauge railways forward from about that depth which were, in many places, combat railways of that gauge. They also paralleled good roads and, frequently, canals.

A function of the Services of Supply, or the assimilated organization, was to bring up the supplies to points within convenient reach of the troops. On the Western Front, standard-gauge and meter-gauge railways, navigable waterways, and roads were used for the bulk shipments, and the rail, water, or road-heads were as far forward at any time as they could be worked. Early in the war these were generally nearer the front than they were later, when heavy artillery was commonly used. The most important instance of long-range shelling by mobile guns was the shelling of points in Longuyon and elsewhere on the German main supply line in the closing fortnight of the war, carried out by the American railway naval batteries from the tracks in the northerly environs of Verdun. The ranges exceeded 20 miles.

The forward areas at the front, where the tramways were used, comprised a belt from 2 to 3 miles in depth on either side of the battle line. They were under intensive enemy observation, to the smallest detail of visible activity or the least sound that could be heard, and were more or less devastated, depending on the liveliness of the sector. They were occupied by the infantry divisions in the line, which also operated the tramways. The devastated area, including the zone between the organized front lines ("No Man's Land"), averaged about 5 miles in depth, and that was about the average distance between the light railway forward dumps of the opposing sides. Following an advance, the light railway troops pushed the tram lines forward with great rapidity and at the same time they brought up by tramway materials for road work in the devastated area, ammunition to the advance artillery positions, and carried on the work of improving the tramway roadbed and clearances so that

Mr. Perry.

locomotive-hauled trains could go forward. The lateral tracks at the rear of the divisional areas on the map (Plate XXVI) suggest the location of the forward light railway dumps; also that of the light and heavy artillery position zones. In any sector under preparation for an advance where no tram line had been located suitably to connect forward, or where conditions had changed the relative locations in this respect, the light railway troops built one or more such lines with the sole view of pushing them forward.

An intermediate area on either side of the battle line, to a depth of about ten miles, was the light railway distribution zone. This was the great dump area of corps and army, for artillery and engineer supplies. In the rear areas the light railways tapped the different supply heads of the army, with break-down connections to alternate heads. The vulnerability of all field railways was decreased by the use of many lateral tracks, which were equally useful as short-cuts.

Elsewhere on the map the German field railways formed networks of overlaid systems. That opposite Verdun suggests the extraordinary offensive-defensive ground organization at the tip of the salient, here in contact with the Hindenburg lines of field fortifications in the region of French Lorraine, which they enveloped. These may be traced roughly through the light rail-heads in the general direction northwest from Thiaucourt to Stenay, or by the battle line at the base of the St. Mihiel salient.

The German left on the Verdun salient, or the French left on the St. Mihiel salient, as the front may be viewed, occupied difficult ground for operations on a large scale in either direction. Northwest of Combres the Germans were in contact with the permanent outer defences of the French frontier—a line of forts connecting the fortresses of Verdun and Toul, here occupying the high ground east of the Meuse River and commanding the plain of the Woevre. At Combres and at Apremont the battle line entered the heights, cutting the Meuse Valley communications of the fortress of Verdun. The railway line —Commercy-Apremont-Woinville-Heudicourt-Vigneulles-St. Maurice-Combres—before the war a meter-gauge railway through Eix and Ornes to Montmedy, meandered the plain at the foot of the heights, which rise more than 300 ft. above. At Vigneulles there is a hole or valley through which a small stream, the Ruisseau de Creue, flows from the plain to the river. The Germans built a standard-gauge branch from Chambley, on the main line, crossing the Woevre to a point between Vigneulles and Creue at the entrance to the hole, which was doubled by light railways that tapped both the main line and the other standard-gauge railways out of Metz. At the end of the branch, close under the heights, they built a large depot and light rail-head; their light railway yard was located at Billy-sur le Cotes, nearby, and there were ammunition dumps, hospitals, and cantonments well apart

in the same area. The artillery in the heights mostly faced the French in the Valley of the Meuse. On the reverse slopes—toward the plain—were improvised billets. The field railways in the heights comprised two systems, one north and the other south of the hole. The system north was reached by funicular lines, from the Billy Yard and from the depot, near Creue, and by one grade line in the shape of a horseshoe curve, toward the St. Remy Woods. The system south was reached by two lines, one a grade line that climbed the southerly slopes of the Creue Valley, toward Chaillon, and the other a line that occupied the reverse slope at Heudicourt where the grade was about 20 per cent. Mr. Perry

The forward areas sloped irregularly toward the Meuse and could have been reached directly only by way of the Creue Valley. The French had good observation in that valley; a few gas shells judiciously placed in the daily shelling programme could have compelled a relocation of the supply approaches, had the valley been much used. These considerations will illustrate the following point: The location of railways in the combat area is a tactical problem and then a technical one, for which reason plans for railway lines came under the supervision of Staff agencies whose business it was to know all about the enemy and our own troops, situations, intentions, and the like, including the supply arrangements. There was not the situation of one service doing one thing, and another something else, each according to its own ideas or traditions; but all were brought together and under the same orders through a staff that possessed enormous facilities for keeping in touch with the needs at every point and at every hour and the authority to direct, in the name of the command, what should be done. For the first time in the history of the American Army, every activity of the American forces in France came under General Staff control.

Toward the Toul front were elements of a line of defense that paralleled the rallying line before referred to, from the Moselle River to Thiaucourt, running thence in a southwesterly direction to the foot of the heights, and may be roughly traced through the light rail-heads in the general direction of Woinville, which were in front of this position. The group of German railways east of Thiaucourt were in broken ground above the Moselle.

The French rail-heads appear on the map as farther back of the battle line than the German heads. The German defences were organized heavily on the first line, the French some miles back. At Flirey, the French outposts were as close as 50 yd. to the enemy trenches, but the battle line was in rear of Bernecourt, 4 miles back. Moreover, many of the French light railways served the permanent forts around Toul and Verdun. The map (Plate XXVI) is not an average section of the front. It shows the most vulnerable section of the German front,

Mr. Perry. which will explain the great mileage of German railways there; but the French Third Army alone had 500 km. of light railway lines in its area. The American forces built about 200 km. The Germans built their light railways of materials from Belgian meter-gauge railways which they had dismantled for the purpose; they built their tramways of materials fabricated for the purpose.

The Toul front, St. Mihiel to Nomeny, was the front of main attack on the St. Mihiel salient. The standard-gauge railway, Toul-Pagny-Sorcy, was and is the main line of railway between Paris and Nancy. The lines converging to the rear meet at Neufchateau, the American main supply head of standard-gauge railway. Sorcy was an important forward rail-head; in so far as operations planned were carried out, it was most important. Sorcy, however, was not the only rail-head; there were others, both in rear of the Paris-Nancy line and forward of that line, as far forward as the battle position in rear of Bernecourt.

A rail-head is essentially a main track, a side track, a platform doubled by the side track and a good road circuit, and a small amount of storage space. For troops, supplies (food), ammunition, engineer materials, etc., the rail-heads were at different points, usually, and provided different facilities. Were a rail-head to provide the facilities necessary for handling all kinds of army traffic, it could not be worked for all at the same time, nor for any two of them regularly, though it was sometimes necessary to receive occasional shipments of different kinds at the same rail-head, not a busy one. Supply heads were generally farther forward than the troop heads and as near as possible to the center of the troop area in any case, the troop rail-heads often being on the strategical railway or *voie-de-rocade* nearest the front. Divisional artillery could be handled at a troop rail-head that could handle the horsed transport. Tanks could be handled wherever a good ramp could be had, and the Tank Corps aimed to increase the scope of its activities by providing portable ramps for the tanks. Railway artillery required sidings or spurs, not classed as rail-heads.

The Sorcy light rail-head was a supply head, disposing of two side tracks, platforms, light railway tracks and a road circuit, and had a storehouse. It was located so as to serve the Toul front and the German tracks in the Woevre, but not the Meuse-Argonne front nor the front between Metz and the Vosges.

The connecting link between the supply or other rail-heads and the trenches was a multiple one, and of different kinds of communications; but the trenches belong to the stationary phases of the war. In war of movement there were no light railways after the trench supply area had been over-run. The Germans, in Picardy, took over all the light railway area shown on the map (Fig. 1) and, in addition, ground to a depth of about 20 miles beyond the rearmost control of that system in

which there were no light railways when they took it over. Based on a situation of movement, road transport throughout the war was and will always be the connecting link between the supply heads and the troops. When a division is in the line, its supply transport waits in the rear, if there is nothing else for it to do, to rejoin the division and replenish it in an advance or during moves and rest periods. The divisional supply trains can make 100 miles per day on a circuit, if necessary. They require good roads, however, and enormous maintenance to keep them good. Mr. Perry.

The minimum rail requirements of the front were, one standard-gauge line forward in each corps area, doubled by one light railway line terminating in a broad loop in the rear of the divisional areas, and one good tram line forward in each brigade area. The minimum road requirements were, one good two-day circuit (for one-way traffic) in each corps area and in each divisional area, together with good side roads for the horsed transport and light automobiles, pack tracks for the pack mules, and paths for the carrying parties. This much was needed to work all the available transport in the normal way. In the same areas the required lines paralleled each other, with frequent spurs, as from rail to road dumps and from road to rail dumps, and cross-connections, between lines of adjacent sectors and those of the same kind in the same sector, when there were more than one (the Germans aimed at two light railway lines of supply per divisional sector). In the back areas from two to four railways for strategical moves were the main strength of the different fronts.

The rail and road arrangements, however, were practically imposed by the shape of the front in its relation to the shape of the existing systems of railways and roads; and the same is true of the canals. Much work was done after the line had stabilized to bring these systems into the service of the front by constructing combat railways and roads in sectors and also in the back areas, so that railway trains, for instance, could be brought by roundabout lines to places which would otherwise be cut off. The British front was the most difficult to get around by railway.

Light railways supplemented the motor transport columns of the rear and the motor transport trains of divisions, as well as a large but uncertain amount of motor transportation of corps and army which otherwise would have been necessary. The standard-gauge railways were brought up wherever possible so as to be within reach by the divisional trains, but they were not always available when needed most. The same may be said of good roads. Such communications as railways and roads facilitated an enemy advance as well as area operations. On the Meuse-Argonne front there were three American corps in line, of which the center corps had no road at all which was

Mr. Perry.

useful and the right corps had only one road, a muddy one. The left corps had a good road, along the easterly edge of the Argonne Forest, and this road, after repairs, had to take the army traffic which was brought to it obliquely from the center.

It is to be noted that a connection with the Chambley-Vigneulles Branch of standard-gauge railway might have been made in the Woevre by pushing a standard-gauge line forward along the right of way at the foot of the heights. Such a forward line was built as far as Woinville, at the time of the Armistice—branching from the Paris-Nancy line at Commercy. Also, to that time, the light railways out of the Sorcy rail-head could not be worked much farther than Vigneulles, within the old salient, serving the troops in the line. Sorcy, 10 miles behind the old front, was 20 miles behind the new one, between Nomeny and the tip of the salient at Verdun; but Vigneulles was too near to be used as a forward standard-gauge rail-head.

Mr. Hadden.

GAVIN HADDEN,* ASSOC. M. AM. SOC. C. E. (by letter).—It may not be out of place in a discussion of this interesting and valuable paper, to mention some of the other types of transportation which were developed by the British Army for use in the extreme forward areas in conjunction with the light railways.

Mr. Pugh has divided the light railways as operated by the American Expeditionary Forces into three zones, the third of which he terms "Tramlines at the Extreme Front, Using Animal or Man Power". This zone in the British transportation system had become of such importance during the period of fixed trench warfare that early in 1918 a special department was organized, separate from the Department of Light Railways, and given the name of "Foreways." This department, under the command of Col. Battye of the Royal Engineers, had a school and experiment station in full operation at the time of the beginning of the German drive in March, 1918. Some of the methods of transportation which were being developed at this time were extremely interesting, and might well be applicable to civil uses. In March, 1918, the writer made a brief report on some of these types of transportation to Maj.-Gen. W. C. Langfitt, U. S. A., who at that time held the office of Manager of Light Railways, as well as Commander of the American engineers with the British Expeditionary Forces. The writer lost all his personal records in France, and must rely, therefore, on his memory for descriptions of the various forms of transportation equipment. Complete details, however, may be found in the records of the War Department.

Tramways.—The tramways consisted simply of a light form of light railway, and have already been described briefly by Mr. Perry.

* New York City.

Mr Hadden.

Mono-Rail Car and Track.—The mono-rail form of transportation had been completely designed and was about to be put into experimental operation when the rapid advance of the enemy caused all further development to cease. The design called for a single 9-lb. rail, without specials, to be laid on short pieces of tie or any other material which might be available. Its principal advantages were that it required very little grading and no special work, and that it was easily transported, quickly laid, and quickly repaired. It was claimed that short breaks in the line could be crossed without any rail.

The car for this track was of special design, having two double flanged wheels in tandem, with the body, about 7 or 8 ft. long and 3 or 4 ft. wide, set very low between them. A 6-ft. horizontal pole, about 4 ft. off the ground and set at right angles to the track, at the head end of this car, in adjustable holders to allow it to be shifted from one side of the track to the other, was designed for balancing. With this leverage and the low center of gravity, one man could easily balance a heavy load. Either man or animal power was to be used for hauling.

Hamilton Ropeway.—The Hamilton ropeway was the invention of a lieutenant in the British Army from whom it received its name. It had been used for some time with great success before the writer saw a section in operation at a forward battery position near Maroc. The equipment consisted briefly of two parallel wire cables $\frac{1}{2}$ or $\frac{5}{8}$ in. in diameter, supported on upright standards. From these cables were suspended trains of carriages loaded with ammunition, etc., each on two grooved wheels in tandem and drawn usually by man power. The standard consisted of a piece of 3-in. pipe, about 7 ft. long, bolted at the lower end to a steel angle base, and at the upper end to a steel angle cross-arm. At each extremity of the cross-arm a cableway was fastened, one cable being used for operation in each direction.

The ropeway was erected in independent sections about 200 ft. in length, so that if the line was damaged by shell fire only one section would be put out of commission at a time and could be readily repaired. The cables were anchored to "dead men" at the end of each section, the terminal cross-arms being designed so that the cables from both directions passed over them in the same straight line and were fastened with special clips to form a continuous track. The carriages were coupled together in trains of a length equal to the average span between standards, so that the grade resistance caused by the sag in the cables was approximately balanced. All parts of the cableway could be easily handled and assembled under almost any conditions. The fastenings were designed so simply that they could be set up at great speed at night. The cables were drawn taut with block and tackle.

Another great advantage of this type of transportation lay in the fact that it formed an invisible target for direct fire and could only

Mr. Hadden

be traced on aeroplane photographs after a path had been worn by the men hauling the loads. When the ropeway had been in operation long enough to be plainly visible in this way, it could be shifted a short distance to new ground.

Leaming Ropeway.—The Leaming ropeway was similar to the Hamilton ropeway in design, with the principal differences that a power cable was used for hauling instead of man power and that the standards were X-shaped and built of wood. The advantage of this ropeway over the Hamilton ropeway was principally the fact that it saved man power, and also saved casualties where exposed positions were crossed. It was, however, not nearly so satisfactory as it was subject to frequent break-downs and the whole system would be thrown out of operation by a break at any one point. It was, moreover, much more cumbersome and difficult of erection, and motive power was not always available.

The principal aim of all these systems of transportation which were being developed by the British was the saving of man power. The shortage of men was so acute that every effort was made to furnish mechanical aid to muscular effort. One of the simplest and yet most effective aids of this nature was an ordinary wheelbarrow, fitted with a small pilot wheel forward of the main wheel and designed to clear the ground about ¾ in., in normal position. This contrivance was effective for hauling loads over uneven ground, and particularly on duckboards in the trenches. With a heavy load, the ordinary wheelbarrow would sink into a small shell hole or drop between the duckboards, where one or two were missing or broken, and it would be extremely difficult for one man to haul it out. With the addition of the small pilot wheel, however, a load could readily be raised at the farther edge of the hole in much the same way that a baby carriage is raised from pavement to curb.

Mr. Jonah.

FRANK G. JONAH,* M. AM. SOC. C. E. (by letter).—The writer is greatly pleased with the interesting discussions which his paper has elicited, and expresses his thanks to those who have contributed so much of value to the subject. Taking the discussions in order, it is desired to refer in turn to points brought out by the contributors.

It is true, as stated by Mr. Hay, that the French had developed the light railway prior to the World War, but for use in and around permanent fortifications. There were some short lines connecting Toul with outlying forts, also some at Epinal, Verdun, and doubtless elsewhere. For instance, at Toul there was a line leading from the arsenals up to the fort on the summit of Mont St. Michel, a hill 300 ft. high, immediately north of the city, on which the French maximum grade of 10% was used. The writer, with a party of officers, made the ascent to Mont St. Michel in December, 1917, in a wagon or gondola

* St. Louis, Mo.

car, hauled by a Pechot locomotive. However, for tactical use, light railways had not been considered until the fact was demonstrated by actual experience that the front line could not be adequately supplied by motor transport. As to the standard section of rail, the writer knows that various weights were used, both by the French and Germans, namely, 5, 7, and 9 km. per meter. Mr. Jonah.

The studies of results by American engineers led them to believe that bolted track was better than riveted track where steel ties were used, because when a section of riveted track was damaged by wreck or shell fire, the whole section had to be taken out; but with bolted track, the bent rail or bent tie could be readily removed and repairs quickly made. In December, 1917, the writer visited the French light railway shops at Chartres, and noticed a large reclamation yard, where German prisoners were cutting apart bent up and twisted sections of riveted track which had been salvaged from the front. He also noticed German prisoners assembling new bolted track, of rails weighing 20 lb. per yd., with 8 steel ties, 1 m. long, to 5-m. section of track, which material was of American manufacture. This track was of 60-cm. gauge, and was being sent to the Italian front. The prisoners were given task work, and 4 men were required to bolt up 27 sections in 9 hours; thus, 48 men assembled a little more than 1 mile of track per day.

Col. Green has treated of the necessity of light railways in forward areas, and speaks from experience, as he had charge of the operation of a system of these lines on the British front in Picardy, in the autumn of 1917, and worked so close to the front lines that he used both steam locomotives and gasoline tractors and had much experience in repairing lines damaged by shell fire.

Gen. Black has called attention to the lack of preparedness when the United States entered the war, and pays a deserved tribute to the engineers from civil life who so promptly responded to the call, and who, working under the small nucleus of the Corps of Engineers of the Regular Army, were able to evolve such a large and efficient body as the Corps of Engineers, A. E. F., at the close of the war. The writer believes in universal military training and knows, too, that the efficiency of the men in the Corps of Engineers is the result of their years of experience on the great public works of the country.

It was the writer's great privilege to serve under five very distinguished members of the Corps of Engineers of the Regular Army. They were all good engineers, had handled large works in the United States, the Philippines, Panama, and Cuba, and knew how a job should be handled and how men should be handled, and the writer believes with Gen. Black that the status of the Engineer Corps should not be changed with respect to its employment on public works. He believes

Mr. Jonah. that its sphere of employment in peace times should be enlarged, and that a young graduate from West Point could profitably spend a year, for instance, in the transportation department of a large railway system.

It is a pleasure to pay tribute to the splendid work of Col. Wilgus. His Commission, after a study of only a few weeks, cabled a requisition to the United States, early in July, 1917, for light railway track material and equipment, and it is only the simple truth to state that it was adequate in quantity and suitable in quality for all the needs of the American Army up to the signing of the Armistice. In this connection, great credit is due also to Gen. Felton's organization in Washington for its prompt action when the requisition reached it. This organization hurried out the designs, placed orders, secured the material, and had it shipped with no delay whatever.

It is, of course, a fact that much additional equipment and track material was ordered and some received in France prior to the cessation of hostilities. This was done, however, on the assumption that the war might last through 1919, and it enabled the United States Government to supply the French with considerable quantities of material, and a great quantity was piled up in American storage yards when the war ended.

The writer's experience with this material enables him to state that it was entirely satisfactory when properly used. Perhaps a gauge of 30 in. would have been better, as giving greater stability to track, but that was out of the question with a 60-cm. gauge in use by all the other armies. Several of the discussors have referred to the frequent derailment of the locomotives. This was due, usually, to inexperienced men trying to run them too fast on poor track. One lesson is fundamental, track must be ballasted and kept in good surface; another is that trains should not be run faster than 8 miles per hour.

As to the use of the light railway after position warfare ceased and open warfare was resumed with the retreat of the Germans in the closing months of 1918, the writer contends that the light railways did not cease to function by any means, and were as necessary as in the previous months. It will be seen by reference to the map (Plate XXVI) that the Germans had a very great mileage of light railways which they were unable to destroy in their retreat. It was only the work of a few days in some cases, and a few weeks in other places, to connect the American system with that of the enemy and haul supplies to the troops in the occupied area formerly held by the Germans. Thus, supplies were hauled from the Sorcy rail-head to Conflans, about 60 km. over light railways, and from Bernecourt and other rail-heads long distances into the regions formerly in the hands of the enemy. To be sure, this was not an ideal way of hauling supplies. Light railways were not designed for long hauls, but in the absence of standard-gauge lines (the Germans had greatly damaged them) and of sufficient motor

transport, the light railways saved the situation; and, again, their construction would be justified, if for no other reason than their use in salvage operations in the devastated areas. Mr. Jonah.

Mr. Dunham has certainly contributed something of interest, and it will doubtless be news to most engineers to learn that 2-ft. gauge lines are used successfully for the regular transportation of passengers and freight in the United States. The lines in the State of Maine, which he has described, must be very well constructed for the speed made over them. Their grades and curves conform to the practice generally followed in France.

As to light railway artillery trains the writer saw such a train that was regularly used by the French. It was in the shop at Toul, and had just returned from the front. In it were mounted 6-in. guns on flat cars provided with drop sides, or outriggers, to steady the car when the gun was discharged. The French moved this train out at night, shelled the Germans awhile from one position and then moved to another, and claimed that it was a great success.

The writer is sure that Capt. Pumphrey will agree with him that most derailments were due to bad track and excessive speed, and he will also agree that during the time the 21st Engineers were operating the light railways from Sorcy, prior to the St. Mihiel drive, or from March 1st to September 1st, 1918, comparatively little trouble was experienced on this account. The track was well kept up during these months, and after the drive, the connecting tracks to the German lines might have been more quickly constructed had sufficient troops been available. The writer believes that the importance of these connections was not fully appreciated at General Headquarters, and, consequently, troops and material were not at hand to make them promptly.

Replying to the criticisms of Capt. Hoyt: The light railway cars were heavier than they should have been, and, doubtless, some improvement could be made in the locomotives and tractors, but such defects as they had were by no means fatal, and the difficulties experienced were the fault of the men running them, rather than the equipment itself. As to speed at which tracks could be constructed, the time given by the writer is for a road complete, including ballast; whereas, Capt. Hoyt gives some figures for track-laying on an old road-bed, with such added work as was entailed in filling shell holes, mine craters, blown-up culverts, etc., which is not comparable with the work of building a new light railway.

The location of the railway shops at Abainville served the St. Mihiel and Argonne fronts better than any other location that could have been selected to serve both, and when established was 37 km. back of the line. Location closer to the enemy's front line than 30 km. was not permitted. These shops were so nearly complete that they were

Mr. Jonah.

able to set up and keep sending a constant stream of equipment and supplies of track material to the First Army during the Argonne battle. It is true that it may have taken three days to get it up on its own rails, but that was much better than not getting it at all, and to have undertaken to load light railway track material and equipment on standard-gauge cars and send it around that way would have meant weeks, instead of days. There was a great shortage of equipment on the standard-gauge railways, and, often, it took days to get a car for loading.

The writer noticed that various systems of light railway on the French front were not connected. Each system radiated from some standard-gauge rail-head, and there were no connections except such as might be had by transferring equipment or material at the broad-gauge rail-head and moving it around to another sector on the standard-gauge track. The writer suggested the advisability of connecting the various light railway systems, which could be done by building short stretches of 60-cm. track, and it was such a connection finally made that enabled light railway equipment and track material to be taken from the St. Mihiel Sector to the Argonne.

The reports required by the Department of Light Railways were for the purpose of keeping a necessary quantity of supplies moving to the front and placing orders for a sufficient stock from the States to take care of the requirements. The Department did not expect that the American operations would be helped materially by fuel captured from the Germans, but from such reports were enabled to form a very fair idea of needs long before anything was captured from the enemy.

The writer disagrees with Capt. Hoyt that ample troops and material were provided for making quick connections across "No Man's Land", and refers to the experience of Capt. Pumphrey at Flirey. The writer made some personal observation on the ground of the progress made in changing the meter gauge to standard gauge running north from Commercy. There were not enough men on that job to put it through in anything like a reasonable time; and that, as has been pointed out in the discussion, was one of the partial failures of American engineers, they did not extend the standard-gauge lines as quickly as they should, largely by reason of a limited number of troops on railway construction.

The writer is indebted to Maj. Pugh for his very complete and able discussion of the subject. He is particularly pleased that Maj. Pugh has treated so fully of the work at the front, and has so clearly emphasized the different standards of construction that must, of necessity, prevail. The views accompanying his discussion add greatly to the value of the paper as they give a picture of conditions as they existed in the extreme forward areas.

Mr. Jonah.

The writer believes, with Maj. Pugh, that 30 in. would be the proper gauge for a light railway, and sections about 16½ ft. long with eight ties bolted to the track would be ideal for work at the extreme front; and, perhaps, to make up for extra weight in the tie, the rail section might be reduced to 20 lb. per yd. It is desirable to have sections of track that can be handled readily by a squad of men. The 5-m. section with a 25-lb. rail used by the Americans, weighs 461 lb.

The writer believes that the suggestions of Lieut. Gregg, referred to by Maj. Pugh, as to light railway equipment, are good. The French light railway truck was the most efficient piece of equipment used by any of the armies.

TYPICAL ARRANGEMENT OF LIGHT RAILWAYS FOR AN ARMY.

(French Manual, April 1st, 1918)

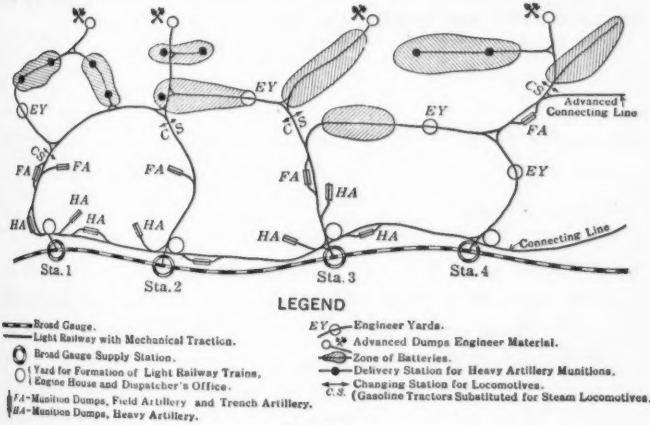

FIG. 22.

The discussion on track shows clearly the necessity of liberal quantities of ballast. In a country as muddy as Flanders, where the British had about 40 men to 1 mile on maintenance, a railway of any kind is soon impassable without ballast. A highway also requires ballast in such a country, and as it was raining a greater part of the time in France, the light railways were built and operated under the most severe natural obstacles. It is conceivable that in another theater of war these great difficulties due to almost incessant rainfall would not obtain.

Maj. Perry has stated very clearly the conditions that obtained at different times on the sectors occupied by the Americans. No doubt the ideal arrangement of a system of light railways would be as suggested by the French in their Manual of April 1st, 1918. Fig. 22

Mr. Jonah. gives a clear idea of the use to which a light railway system might be put.

Sorcy, of course, was only one rail-head and designed to serve a certain sector, and has been described as typical of what a rail-head should be.

The writer fully agrees with Maj. Perry that a standard-gauge line should have been rushed north from Commercy to Vigneulles where it would have connected with a standard-gauge line constructed by the Germans; this might have been done by converting the meter gauge to standard gauge, which work has been referred to and which was carried north only as far as Woinville.

The writer is pleased with the discussion of Mr. Hadden, as he brings out fully some types of transportation in the forward areas that were being developed and would have had an extended use in the American Army had hostilities continued.

Paper No. 1452.

REPORT ON CAUSE AND CORRECTION OF FOUNDATION TROUBLES OF BOX FACTORY AT NATCHEZ, MISSISSIPPI.

By C. E. Smith, M. Am. Soc. C. E.

With Discussion by Messrs. Charles H. Miller, J. E. Willoughby, George L. Dillman, and C. E. Smith.

Synopsis.

During 1917 a large box factory was built on a bench of land adjoining the east bank of the Mississippi River, at Natchez, Miss., 75 ft. below the top of a bluff and 150 ft. above the river. The owner was not represented on the work by an engineer or building inspector. The work was carried out by an "engineering contractor" on a cost-plus-fee contract. Following the completion of the plant, settlement occurred in the foundations under practically all the buildings and machinery, and it appeared that the entire building site would slip down the hill.

Various causes for the settlement were suggested, such as erosion of the Mississippi River bed under water, settlement of the ground, due to fine under-soil carried out through springs by the ground-water, slipping of pervious strata above on the impervious stratum below, etc. Investigation disclosed that neither the erosion of the Mississippi River nor the action of escaping ground-water caused the trouble, which was found to be due to softening of the top 20 ft. of soil by water that could not escape through impervious blue clay under it.

The trouble was corrected by excavating trenches through the top soil to the blue clay, installing porous tile and wood box-drains and back-filling the trenches to the surface with cinders and gravel containing a large percentage of sand. Immediately following the completion of the drainage system, all ground movements stopped, the defective foundations were corrected, additional boilers, engines, and other facilities were installed, and no further foundation trouble has occurred. A total expenditure of about $20 000 for drains stabilized the soil and made it possible to continue the operation of the factory.

More than $25 000 had been spent in a futile effort to stop the movement by driving timber piles into the moving ground, and the plant was operated at very low efficiency on account of frequent shutdowns, resulting in large operating deficits each month. Immediately following the stabilization of the foundations the plant overcame all deficits and showed a profit.

During 1917 a large factory for the manufacture of wood boxes, tubs, and veneer was constructed under contract on the east bank of the Mississippi River, at Natchez, Miss. The general plans were prepared in the office of the owners at Chicago, Ill., who were represented on the construction work by a bookkeeper; the future plant manager visited the work occasionally. The owners did not have an engineer or building inspector on the work, as it was thought that the "engineering contractor" would automatically provide the engineering and inspection. Later developments indicated that special engineering knowledge and advice during the construction period were conspicuously absent, and nearly resulted in the wrecking of the plant.

Ground Conditions and Movements.

At the site of the factory the Mississippi River has a vertical rise and fall of about 50 ft. The bank slopes upward about 1 in 5 for 750 ft. back from the high-water line to the highest ground 150 ft. above. A cross-section of the bank between the river and the top of the bluff, at the site of the plant, is shown in Fig. 1.

The surface of the sloping bank consists of a thin layer of black loam, under which is yellow clay of indefinite depth. In this clay appear, at several depths, and in irregular thicknesses and extent,

various strata of coarse sharp sand, fine quicksand, mixtures of this fine sand and clay, and sloping layers of blue clay. The mixture of fine sand and clay is very firm and hard when dry, but when saturated with water it becomes a typical quicksand.

For many years, beyond the memory of the oldest settler, this typical Natchez river bank has been sliding or flowing toward the river, causing continual disturbance and subsidence of the ground surface on the slope. The movement of the ground was a miniature reproduction of glacial action. A typical cross-section at a point where the greatest movement took place is shown in Fig. 2.

Residents over 80 years old remember being told of the time when the slope was higher and level and occupied by buildings. It appears that the high ground originally extended out to a bluff on the river bank, and that the present slope is the result of the sliding to which reference has been made.

At extreme low water, or zero gauge of the Mississippi River, a porous stratum of cemented gravel and sand with a small mixture of iron ore, locally referred to as "ironstone", outcrops along the entire Natchez water-front and gives forth an abundant flow of clear cool water through numerous springs.

This emergence of the underground water 200 ft. below the high ground above has been commonly held as the reason for the sliding and settling of the sloping bank. A careful examination of the porous stratum and of the springs, together with other conditions and information, convinced the writer that the sliding and settling were not due to this cause. The water emerging from the porous strata comes out perfectly clear and does not carry any sediment. If, in fact, fine sediment were being carried out from deep levels by this underground water, undoubtedly caves would be formed, which, in the fine, easily broken-down soil that overlays the cemented gravel, would ultimately result in chimneys and sink-holes. There are no such chimneys and sink-holes at Natchez.

Bank Erosion by Mississippi River.

Another theory which was advanced to account for the sliding ground is that the erosion of the river bank below low-water level caused the bank to subside and gradually flow toward the river. This theory was strengthened by the fact that within the memory of present

residents of Natchez the river has made extensive inroads on the lower portion of the city. The present high ground on which the city is located was formerly separated from the river by an area of comparatively low and level ground, four or five city blocks in width, fully occupied by buildings, known as "Natchez-under-the-hill".

Approaching Natchez from up stream, the river makes a long sweep or bend and takes a direction nearly at right angles to the bank, then turns in another bend to follow the direction of the high ground. The low ground of "Natchez-under-the-hill", having been located in the bight of the bend, was eroded until it nearly all disappeared, barely space enough remaining for one street on the side-hill between the water and the bluff. Further erosion of the bank was prevented by mattress and revetment work placed by the United States Government. The United States Engineer Corps took numerous and frequent soundings along the front, a study of which indicates that since the revetment was placed, no further erosion has taken place. The bank down stream from the revetment, opposite the site of the factory, has not eroded to any appreciable extent, and it does not appear that the sliding and subsidence of the sloping bank above high water was due to the erosion of the banks by the river. The river is quite deep, the bed being 60 ft. or more below low water.

According to Mark Twain's reference to "Natchez-under-the-hill", its disappearance might have been a well merited fate. In his "Life on the Mississippi", about 1880, he refers to it as follows:

"Famous Natchez-under-the-hill has not changed notably in twenty years; in outward aspect—judging by the descriptions of the ancient procession of foreign tourists—it has not changed in sixty; for it is still small, straggling and shabby. It had a desperate reputation, morally—in the old keel-boating and early steamboating times—plenty of drinking, carousing, fisticuffing, and killing there, among the riff-raff of the river, in those days. But Natchez-on-top-of-the-hill is attractive, has always been attractive."

Plant Site and Buildings.

A site for the factory was prepared by leveling the slope about 60 ft. below the top to a bench approximately 350 ft. wide, the deepest cut in the bluff amounting to nearly 30 ft. and the highest fill about 25 ft.

The factory buildings, covering about 2 acres, and including the boiler-house with brick stack, engine-house, veneer mill, kiln veneer dryers, storage sheds, box and tub factories, soaking vats, elevated water-tanks, and appurtenant log conveyors and tramways, derricks, and saw-mills, were built on the graded ground. The construction was completed, and operation of the plant commenced early in 1918.

Failure and Movement of Foundations.

Less than a year after the completion of the plant, and during the rainy season, the ground sheared vertically along several lines normal to the slope of the hill-side, with a settlement of from 2 to 15 ft., and slid down the hill-side, carrying large sections of surface earth with growing trees as far as 200 ft.

A typical crack in the ground preceding a slide is shown in Fig. 4. The lower slope of the sliding ground is shown in Fig. 6.

Shortly after operations commenced, the foundation walls under the boiler-house broke, and the river end settled about 1 ft. and moved toward the river 1 ft.; the brick walls fell down, the brick boiler settings of two 300-h. p. boilers were shattered, and the boilers pulled away from the breeching. The 90-ft. brick stack settled and caved slightly, and the water-tank footings showed a slight settlement.

The plant was originally operated by a 550-h. p., Corliss engine and line shaft. The engine foundation settled and threw the engine out of setting. The concrete foundations under the 6-in. jack-shaft settled several feet and slid 5 to 10 ft. entirely outside of the engine-house. The engine-house foundations on the river side settled and slid completely out from under the engine-house. The movement of these footings is indicated in Figs. 7 and 8.

Practically every footing under the storage shed settled and moved out of place. The outside row on the river side settled over 15 ft. and slid out nearly 30 ft. About seventy footings settled and moved. Figs. 3 and 5 show the nature and extent of this settlement and movement.

The settling ground extended back to the foundations of the heavy veneer mill and planers and the kiln veneer dryers; it broke sewer and water lines, caused frequent long shut-downs, made it impossible to get on a production basis, and, for a while, it appeared as if the

enterprise would have to be abandoned, and the plant moved to another site.

Emergency Repairs.

Ineffectual methods were adopted to stop the sliding ground. Timber piles were driven into the ground, but they were carried right along, tipped over, upheaved and literally thrown out of the ground by the movement, as shown in Figs. 9 and 10.

After closing down for sixty days, the factory was continued in intermittent operation with the greatest difficulty by keeping gangs of workmen all over the plant jacking and propping the buildings on the moving ground. A new connection was made between the unaffected portion of the jack-shaft and the re-set Corliss engine. A new engine, with dynamo, was installed and motor drive put on several machines.

Investigation of Trouble.

After this painful experience had continued for about a year, the situation was brought to the writer's attention for the first time early in 1919, when the owner requested that an examination be made, the trouble diagnosed, the remedy prescribed and estimated, and recommendations submitted for further procedure.

After a careful examination, the writer concluded that neither the erosion of the river nor the springs at low-water level had anything to do with the settlement, but that it was due to local conditions, and that the ground movements and slides could be stopped by a system of under-drains. The filled earth was a very loose mixture and contained a quantity of rubbish which prevented it from packing and forming a hard surface such as would permit water to flow off rapidly. On the contrary, the surface was broken by cracks and depressions which collected the water and caused the filled earth to become rapidly saturated to the depth of the original ground surface.

On this less pervious surface the water collected, saturated the loose loam and clay to a slimy mass, 1 or 2 ft. thick, and started to flow down the slope. Farther down the hill-side at the lower end of the fill, the water came to the surface washing with it a mass of soft mud. As this mud oozed out, the earth above settled and this, in turn, became saturated and started to flow. Where the soft earth at the level of the original ground surface did not flow enough to cause a vertical settlement, it formed a slippery layer on which the loose earth above could slide.

Conditions which were bad enough after weeks of torrential rains common in the lower Mississippi Valley, were made worse by surface drains both for storm-water and for water resulting from the operation of the plant and, after the first slight movement of earth, by a number of leaks in underground water pipes and sewers.

The slide as well as the vertical settlement was further augmented by hundreds of tons of log cores from the mill, which were piled on the hill-sides near the top of the slope. Besides placing a great weight on top of the moving earth, these cores furnished crevices and openings in the ground surface through which the water soaked into the earth instead of running off.

Construction of Under-Drains.

A comprehensive system of porous under-drains, with a combined length of 2 870 ft., was placed under and around the principal buildings of the plant. These drains consisted of tile pipes or perforated wood boxes placed at depths of from 10 to 25 ft. in trenches, which were then back-filled with gravel or cinders. The trenches averaged 30 in. in width, which was as narrow as they could be dug conveniently to the required depth.

Tile pipe of sizes from 6 to 12 in., which could be placed more cheaply than wood box, was used in all lines where the earth was not moving; but at points where movement was taking place it was found that sections of pipe pulled apart too easily, and continuous wood box was used instead. Wherever possible this was kept below the plane of the slide.

This wood box was built of 2 by 12-in. cypress planks, the sides resting on the bottoms so as to make the interior dimensions 8 in. wide by 12 in. high. The sides and top were perforated with 1-in. holes in two rows, at 8-in. intervals in each row. The joints between the side and bottom planks of the box were well caulked with oakum and then covered with narrow lath. These joints were broken so as not to have successive planks in the side to join at the same section at which planks joined in the top and bottom; all were held by 2 by 12-in. scabs, 3 or 4 ft. long, well spiked at both ends so as to keep the box from pulling apart during slight movements of the earth. The lumber used was a low grade of pecky cypress which was found to be quite satisfactory.

FIG. 9.—TIMBER PILES DRIVEN IN EFFORT TO STOP EARTH MOVEMENT.

FIG. 10.—TIMBER PILES DRIVEN IN EFFORT TO STOP EARTH MOVEMENT.

From the lower ends of the under-drains the flow was carried down the hill-side in open flumes of wood, of the same cross-section as the box underground. Points at which the drains came to the surface were selected, on steep slopes, so as to have the drain-pipe or box pass through as short lengths as possible of the surface earth, as this was constantly in motion and tended to pull the sections of pipe and box apart. The open flumes were placed on timber bents spaced 10 or 12 ft. apart. The flume was kept from disjointing at each slight displacement of the bents due to movement of the earth. The bents could be put back in place after each movement without injuring the flume.

After the completion of the under-drains the earth near them, especially on the hill-sides, was graded to slope uniformly toward the gravel-filled trenches through which the water passed to the under-drains.

The flow through the several drains was measured daily during their construction, and that through each drain was found to decrease gradually for two or three weeks after its completion, which indicated that the level of the ground-water was being slowly lowered. The total underground seepage after the drains had been in place sufficiently long to have reached their minimum of flow, and after defects in the surface drainage had been corrected, amounted in the dryest weather to about 12 000 gal. per day from an area of about 4 acres, 2 acres of which are covered by buildings the drainage from which is otherwise disposed of. This was increased to about 100 000 gal. per day in very wet weather.

Movement of the ground stopped promptly at one point after another as the drains at these respective points were completed, until the work was finished. After completion, not the least movement could be noticed at any time. The earth, which formerly was muddy and soggy from one rain until the next, now dries rapidly after each successive downpour and is perfectly stable. The plant, valued at $800 000, in serious danger of ruin, has been made safe for operation by an expenditure of less than $20 000.

Although several months have elapsed since the completion of the drains, there has been no further trouble. The drains were placed

during the early summer of 1919. In February, 1920, the manager of the factory advised as follows:

"I am very pleased to report that even in the face of the continuous rains all through the summer and up to the present time, even in a heavy rain which we had in January, when it rained about 7 in. in two days, there was absolutely no movement in any part of the hill where the drains were put in."

Cost of Drainage System.

The cost of the work was as follows:

Excavation per Cubic Yard:	
Handling earth (in addition to actual excavation, this includes an average haul of 250 ft. for all excavated material)	$2.00
Miscellaneous items (this includes bracing the trench, foreman's supervision, trench-jacks, lumber, and rubber boots)	1.35
Total	$3.35
Back-filling per Cubic Yard:	
Labor (this includes handling of gravel from railway cars to the several drains, with an average haul of 250 ft.)	$1.90
Gravel, including freight	2.10
Total	$4.00
Placing Wood Box per Linear Foot:	
Labor (time of carpenters and laborers building the box, and placing it in the trench)	$0.65
Cost of timber	0.20
Total	$0.85
Placing Tile Pipe per Linear Foot:	
Labor (time of foreman and laborers carrying the pipe from stock piles to the drains, and placing it in position)	$0.20
Tile pipes, including freight	0.35
Total	$0.55
Cost per Linear Foot on All Operations	$7.20

The trenches reached a maximum depth of 25 ft., with an average depth of 15 ft. All trenches were braced. In many places the soil ran through the cracks like soft ice cream.

The unit costs for material and labor were as follows:

Cost of Labor per Hour:

Foreman	$0.75
Carpenter	$0.50
Negro laborers (10-hour day)	$0.25 to $0.30

Cost of Material per Cubic Yard:

Gravel ($1.20, freight $0.90)	$2.10
Cinders (loading and switching charges only)	$0.80
Lumber, pecky cypress, per 1 000 ft. b. m.	$30.00

Tile Pipe:

Size, in inches.	Pipe.	Freight.	Total.
6	$0.19	$0.05	$0.24
8	0.27	0.07	0.34
10	0.37	0.09	0.46
12	0.58	0.12	0.70

Other Plant Improvements.

When work on the under-drains had progressed far enough to convince the owners of success, work was started on the reconstruction of the damaged portions of the plant and on several additions. The old foundation of the drag-saw used to cut the rough logs to convenient lengths for the lathes, had to be entirely replaced and the engine operating the saw re-set. The foundation for this engine and saw was 20 by 28 ft., and consisted of twenty-four timber piles with an average penetration of 25 ft., capped with a 24-in. slab of concrete.

A small saw-mill was built adjacent to the drag-saw. The point of the hill on which this was located had not yet been cared for by under-drains and was still moving at the time the mill was built. For this reason, it was decided to place for a foundation a heavy frame of 12 by 12-in. timbers which could be jacked up and leveled after slight movements of the earth until such time as it would be quite stable, when a more stationary foundation could be placed.

In order to join this saw-mill with the veneer mill and the drag-saw with the boiling vats, conveyors and a heavy timber platform 9 ft. high were built to replace an old conveyor and platform which had been completely wrecked by the slide. All these structures were placed on timber piles, with penetration well into the original solid ground beneath the slide. The piles under each conveyor were placed at 8-ft. centers in each of two rows 5 ft. apart. Under the platform they were at 6-ft. centers in both directions.

All water pipes and sewers were seriously damaged by the earth movement and required extensive repairs. The fire protection sprinkling system was entirely removed from underground and put overhead.

The additions to the plant consisted of two new boiling vats, three new boilers with a combined capacity of 1 100 h. p., a new self-supporting steel stack, 8 ft. in diameter and 135 ft. high, and a new engine and 500-kw. generator. The boiling vats were each 9 ft. by 40 ft. over all, with a depth inside of 10 ft. The walls tapered from 9 in. thick at the top to 18 in. thick at the bottom, and each rested on a single row of timber piles driven at 3-ft. centers. The piles were capped with a 2-ft. floor slab.

The boilers, the stack, and the new engine and generator were not placed on piles, as the earth at these points was considered to be stable enough after the completion of under-drains in this vicinity to use the customary spread foundations of concrete.

Supervision of the Work.

The trouble was investigated and the remedy prescribed by the writer; the construction work of putting in the drains and the foundation work for correcting the defects and for the additional mechanical and electrical equipment was supervised by Assistant Engineers M. H. Doyne, Jun. Am. Soc. C. E., and Mr. G. C. Hetlage.

No contract was let. The materials were purchased by the Box Company, the labor was carried directly on its pay-roll, and worked under the Assistant Engineers. The additional mechanical and electrical equipment was specified by D. MacKenzie, Consulting Engineer, of Chicago, Ill., and installed by Mr. Robert Warmack under the supervision of Mr. MacKenzie.

The investigation, installation of the drainage system, correction of defects, and additions to the plant were carried out under the

general supervision of J. W. Drissen, General Manager of the Box Company.

Conclusion.

The employment of competent engineering assistance during the construction period would have avoided all the later troubles and expense. The employment of competent engineering service immediately after trouble first developed in the foundations would have saved large sums expended in experimenting and would have avoided the greater portion of the operating deficits. The plant could have been put on a paying basis much sooner with a great saving to the owners.

DISCUSSION

Mr. Miller. CHARLES H. MILLER,* M. AM. SOC. C. E. (by letter).—The conditions described by the author are very familiar to the writer and recall the trouble experienced ten years ago or more in this immediate vicinity in an effort to keep the track of the Natchez and Southern Railway Company in reasonably fair alignment without being required repeatedly to throw it back up the hill.

The writer is pleased to note that Mr. Smith reached the same conclusion that was arrived at several years before with respect to the facts that neither the underground water seeping out near low-water level in the Mississippi River, nor the erosion of the river bank below low-water level were the prime causes of the trouble, but that it was due to rain-water which fell on the immediate surface, causing the loose earth to become soft and to slide on smooth layers of clay located at different distances below the surface of the ground.

The treatment applied in this case differed from that described by the author in that a system of open wooden box-drains was placed on the surface of the ground, which was kept smoothed down and sloped toward these wooden drains. This resulted in carrying the rainfall off very quickly and, therefore, preventing it from soaking into the soil; it stopped the sliding, was comparatively inexpensive in first cost, and was maintained cheaply through the efforts of the section gang.

It should be noted, however, that the sliding occurred where the surface area from which underground water could originate was comparatively small, and that there was no big surface farther up the hill with which to reckon. This, the writer understands, was not the case with the box factory site, where, if surface water was to be handled, it would have meant a much greater problem.

It should be stated, also, that the railway line was located along the edge of the bank and, therefore, near the river which at high stages caused wash or erosion at the foot of the bank (the erosion being caused principally by wave wash from high winds) and that, on account of this erosion, it was necessary to construct a brush retaining wall to hold the toe of this bank against the attack of the river.

Mr. Willoughby. J. E. WILLOUGHBY,† M. AM. SOC. C. E. (by letter).—The failure of the piles to cure the slide at the box factory at Natchez, Miss., is in accord with the writer's experience. Piles driven into the moving mass can accomplish the cure of slides only by fastening the upper moving material to a lower stable stratum. If the upper material is of any considerable mass, piles are necessarily ineffective. The anchorage

* Little Rock, Ark.

† Wilmington, N. C.

in the stable stratum is insecure and the piles cannot resist any considerable force applied normal to their length. Mr. Willoughby.

The author has been happy in looking for the cause of the slide and in applying the true engineering remedy, bearing in mind the materials available at Natchez. The writer has accomplished good results in the cure of sliding embankments which support railway tracks by digging open trenches deep into the saturated stratum of the embankment, and filling the ditches with stone of a size that can be handled readily by two men and loosely piled. Such a method is good engineering where stone is available and of small cost.

GEORGE L. DILLMAN,* M. AM. SOC. C. E. (by letter).—This slide seems to have been an ordinary one, with motion extending over years, typical symptoms, springs, etc. The cause is always water. The cure is only drainage. It does not make any difference whether the slip is a small one at Natchez, Miss., larger ones at Culebra, or immense ones at Cow Creek, Tillamook, and the Frazier River. The Pacific Coast is dotted with them, to any one who has his eyes open. Mr. Dillman.

(1) These slides are natural and frequently overlooked by "engineers." The reservoir slide at Portland, Ore., so ably described by D. D. Clarke, M. Am. Soc. C. E., in two papers† before the Society, was such a case.

(2) They are imminent and precipitated by artificial means, such as the Berkeley slide, where a frog pond was a contributing cause and its abandonment the cure.

(3) They are caused wholly by constructions, such as the failure of the Calaveras Dam, the basis of the paper by Allen Hazen, M. Am. Soc. C. E., on "Hydraulic-Fill Dams."‡

These are all slides, and they are all caused by hydraulic pressure. The film of water only has to be thick enough to be continuous in order to act as myriads of jack-screws to lift and crowd the material in front. The resistance is variable—weight and friction—both being diminished by the presence of water, pressure to lift, and water lubrication. The force tending to move is variable, increasing with head until stability is overcome and motion ensues.

Drainage will cure any slide. Any drainage will lessen motion, and sufficient drainage will stop it. All that is necessary is to let the water get away a little more easily (and, therefore, more quickly) than it gets in. That is the principle. Tiling, perforated wooden boxes, drains filled with slag or other material to keep them drains, are only details. Probably the taking away of material as it comes is the most

‡ *Proceedings*, Am. Soc. C. E., April, 1920, p. 525.

Mr. Dillman. expensive cure, but it has been done. With superficial slides it may sometimes be cheaper than drainage.

Mr. Smith's paper is well written. It is good to call the attention of engineers to specific facts. If they can see through the incidents to the principles behind them, that is education. That is what these papers are for.

Mr. Smith. C. E. SMITH,* M. AM. SOC. C. E. (by letter).—An inspection of the site of the box factory in August, 1920, several months after the completion of the drainage work, shows that no earth movements of any kind have occurred since the drains were constructed. Shortly after the slides were stopped, the factory was put on a production basis and is now being operated profitably.

Mr. Dillman is right in saying that it is good to call the attention of engineers to specific facts. It is to be hoped that they can see through the incidents to the principles behind them, which is much to be desired.

Paper No. 1453.

THE PROSPECTIVE COMPETITOR METHOD OF VALUATION OF PROPERTY

By M. L. Byers, M. Am. Soc. C. E.

With Discussion by Messrs. J. P. Snow, C. E. Grunsky, Joseph Mayer, J. E. Willoughby, R. W. Hawley, and M. L. Byers.

Synopsis.

The Courts having ruled that, in estimating the fair value of any operating property, the fact that the property is a going concern must be taken into consideration and that this fact is an element of value, there remains to be devised a method whereby, when the fairness of the rates is in question, this fair value of the property can be estimated with reasonable accuracy.

The method which of late years has found most favor is that usually termed the Cost-of-Reproduction Method. In a general way, value is arrived at by this method about as follows:

From cost of reproduction of the physical property (including a percentage for overhead costs) deduct "depreciation"; to this add going concern value.

The method does not seem to rest on sound economic principles, and parts of the practical operations involved in its use do not appeal to the logical mind. Too much is left to mere personal opinion uncontrolled by guiding principles.

One Court observed that he reluctantly accepted this method because he did not know of a better one. The remark of the Master

in the recent Denver Water Company Case with reference to going concern value is also illustrative. He states:

"There is no absolute standard by which the fair value of this element can be determined, and I adopt $800 000, because no matter how often I have considered the evidence and the arguments my mind always comes back to this amount as reasonable and fair to all the parties."

Further illustration of the difficulties produced by this method is found in the Minnesota Rate Decisions, in which Justice Hughes pointed out in connection with the valuation of the land of the railway that "the assumption of its [the railway's] non-existence, and at the same time that the values that rest upon it remain unchanged, is impossible and cannot be entertained."

Presumably the reproduction theory may be based on the view that this presents the means of estimating what the property under valuation would have cost to construct and develop if present-day conditions as to prices of labor, material, land, etc., density of population, and similar elements had been present during such period of construction and development. This is merely a variation of the theory that the fair value of the property is measured by the investment, whereas, as a matter of economic fact, there is, in general, no necessary relation whatever between the value and the cost of a property.

What is urgently needed at the present time is a rational method of valuation which is in harmony with sound economic principles and does not clash unnecessarily with well-established legal decisions.

The analysis of a new method of determining the fair value of a railroad property, which follows, is founded on seven basic propositions:

1.—A railroad corporation is a private corporation; its property, although devoted to the service of the public, is private property, and its value is as completely under the protection of the Constitution as that of any other private property.

2.—The property of a railroad corporation devoted to the service of the public, and which has been acquired through gifts or donations, or from earnings, is, equally with property acquired from the proceeds of the sale of securities, private property, and as such is under the protection of the Constitution. The surplus from the earnings of the corporation is likewise private property.

3.—Every enterprise subject to regulation is entitled to be permitted to earn such a return as, in the field of free and open competition, would ordinarily accrue to a similar expenditure of energy, foresight, and capital.

4.—A public utility is not entitled to a return accruable solely because of its possession of monopolistic protection from competition.

5.—Every kind of business, without any exception, has an element of value known as going concern value, and such going value is in no way connected with the monopoly or good will value.

6.—The market value of any property results from the use to which it is put and varies with the profitableness of that use, present and prospective, actual and anticipated. There is no pecuniary value outside of that which results from such use. The amount and profitable character of such use determine the value. The measure of that value is its profitableness, present and prospective, actual and anticipated.

7.—The fair value of a property is measured by its profitableness, present and prospective, actual and anticipated, under fair rates.

The analysis results in the development of the Prospective Competitor Method of valuation. The steps recommended in the case of a valuation of a monopoly by this method are as follows:

1.—Production of a prospective competitor (instead of "reproduction" of the property under valuation).

2.—Determination of the rate level which (within that maximum period of time beyond which capital would not be willing to wait) will enable said competitor to earn a fair return on its investment to date.

3.—Determination of the annual net earnings, as of the date of valuation, of the property under valuation and at the rate level indicated in Item (2).

4.—Capitalization of the annual net earnings indicated in Item (3); this capitalized amount is the fair value of the property under valuation. In the case of properties subject to competition, the fair value of all such properties combined (and which combination, consequently, may be treated as a

monopoly) is first obtained by the preceding method; the common fair rate level is also ascertained. By the application of this rate level to the individual properties, the fair return of each is ascertained. Capitalization of such individual fair return gives the individual fair value.

The Competitor Method practically involves no difficulties which are not met with in the Reproduction Method, while it is logical throughout and is based on sound principles of economics.

I. General Principles and Recommended Procedure.

1.—Railway Valuation, Its Theory and Uses.

For many years the railways have contended that the activities of the Interstate Commerce Commission and of the State Commissions have resulted in the lowering of transportation rates to a point where the prosperity of the industry has been seriously interfered with. The Commissions have always replied to this accusation that, while the railroads certainly are not earning the normal rate of return on their capitalization, they are earning, at the very least, a fair rate of return on their fair values; that the real trouble with the railroads is and has been that they are so greatly over-capitalized that a fair charge for transportation produces a comparatively small rate of return on the enormously watered capitalization.

After many years of persistent recommendation on the part of the Interstate Commerce Commission, Congress passed the law calling for valuation of the railroads, which is now in progress. The principal reasons given by the Commission for its recommendation were that the information was needed in connection with the proper execution of its duties, and that the controversy over railway values should finally be cleared up in the interest of all parties.

Since the passage of the Valuation Act, numerous comments have been heard at frequent intervals, among these being statements that it is impossible to find the value of a railway property; that the value, being dependent on earnings, is constantly changing, and that the valuation to-day would be out of date to-morrow; that valuation is useless for rate-making purposes, as the rates do not depend in any

way on the value of the property used; that there is no need for the regulation of railway rates, for the reason that the business itself affords a sufficient check over excessive rates (the very great general increase instituted by the Government as a war measure hardly supports this last contention); and that there are a number of values for the same property, depending on the use to which the data are to be put.

Discussion as to what constitutes fair value has been even more interesting, being largely colored by the interests of those entering into such discussion. The representatives of the States have been consistent in their position that it was their duty to see that the public did not have imposed on it a valuation entirely in excess of the equities of the situation. The railroads have been equally energetic in their efforts to see that the resulting valuation did not arrive at an inequitably small result. Apparently, the Division of Valuation of the Interstate Commerce Commission early came to the conclusion that the railroads were amply able, on all proper occasions, to demonstrate clearly the propriety of deciding in their favor any doubtful points, and that the proper policy was to start out with assumptions which would produce the smallest values; then, through hearings before the Division and before the Interstate Commerce Commission, thrash out the points of controversy to an equitable conclusion.

One of the first claims made as to the constitution of "value" was that it was identical with "cost of reproduction" of the existing property, no allowance being made for appreciation in the value of land; the railroads, being public utilities, were assumed not to be entitled to any unearned increment. As this position apparently became legally untenable, and as the items of cost of reproduction ordinarily overlooked by the casual observer became increasingly important, a tendency developed to assert that value equals, not cost of reproduction, but original cost to date of the existing properties.

The effect on value produced by depreciation and appreciation existing in the property has also been widely discussed. Another of the frequently heard statements in connection with the ascertainment of value is that it is not a matter of fixed rules, this quotation from a decision of the Supreme Court being interpreted to the effect that there are no fundamental principles on which the ascertainment of value can be based, thus still further befogging an already complex subject.

In none of the many discussions on the ascertainment of value has there been any complete analysis of the problem, followed by an attempt to work out principles solidly founded on equity and economics. The present discussion is an attempt to analyze the entire problem and then to build up a rational theory of valuation in harmony, if possible, with such legal generalities as so far have been promulgated.

2.—What Is a Public Utility?

Ordinarily, when a public utility is mentioned, it is understood that a utility supplying water, or gas, or electric light, or transportation to a community, and operating under a charter as a corporation, is meant; that other activities such as farming, manufacture of steel, clothing, food, etc., are not so regarded.

There has gradually developed in the public mind a feeling that public utilities, because of their being public utilities, are subject to entirely different economic laws and have entirely different legal and moral rights and obligations from those of other forms of commercial activity. This unreasoned feeling has been the cause of much misunderstanding and dissatisfaction and of much ill-advised regulation.

Examined from the broad point of view, almost every form of commercial activity is a public utility. The farmer does not raise the greater portion of his crops for his own use, but for the use of the general public. The manufacturer manufactures his product with the same object in view. The essential difference between the so-called public utilities and other forms of enterprise lies in the fact that, in the case of the public utility, there usually enters the element of monopoly, either because of the physical conditions surrounding it or because it is to the interest of the public that the enterprise shall be conducted without competition.

Perhaps a broad definition for a public utility is that it is any industrial activity conducted on such a large scale or under such conditions that the interests of a considerable portion of the containing community are vitally affected thereby.

Looking to the future—bearing in mind the great strides which have been made during the past fifty years in the organization of various enterprises—it seems probable that the time is not far distant when many other enterprises will have arrived at that perfection of organiza-

tion where sufficient control is exercised by a few persons to enable them, if unrestrained, to reap the rewards possible only to monopoly.

It is sometimes stated that an enterprise conducted by a private individual is not subject to Government regulation. This is simply a misstatement of fact. It is also frequently claimed that the giving of the right of eminent domain by the public to certain corporations introduces factors which justify the public in establishing regulations not otherwise equitable. The purpose of the giving of the right of eminent domain has been widely misunderstood and misrepresented. In certain types of industry, in the absence of the right of eminent domain, it would be possible for a single individual to obstruct, or even to prevent entirely, the development of a particular enterprise. Yet it has often been to the public interest to induce private capital to enter such fields. To this end, under various restrictions, the right to condemn property on payment of fair compensation has been granted. To claim that the conferring of this right carries with it the privilege of making later exactions on the grantee is as if a householder employed an artisan to do certain work for him in his house, gave him the key to the house in order to enable him to enter therein, and then stated to the artisan that because of having given him the key he is entitled to pay him a smaller compensation than the going rate for such service.

3.—When and Why Regulation of Industrial Activity Becomes Desirable.

Ordinarily, in industrial activity on a considerable scale, there are four important parties at interest, namely, the owner of the activity (the stockholder), the employee, the individual user of the product, and the general public.

Simply in his capacity of owner, the stockholder is interested only in the amount of profit obtainable from his investment, although that interest extends to the broad point of view and is not confined solely to the narrow limit of immediate results.

The employee is primarily interested in the conditions of service under which he is employed and the compensation received for such service.

The individual user of the service is interested in its quality and in the payment which he must make therefor. If the service which he desires is an unusually expensive one, it is to his interest that pay-

ment for such service be based on general averages of cost, rather than on the cost of the individual service itself. For example, the man who lives at one end of the street car line and has his business at the other end, desires that a single average fare be collected from each passenger.

The general public, although less acutely interested than the three other parties, does have a broad general interest of considerable importance. It is to its interest that the relation between productivity and effort expended (such as the amount of capital utilized) in securing the total production, be as favorable as possible, for by improving this ratio the wealth of the community can be increased. The basis of the division of cost of service is also important. Shall the user pay the entire cost of production of that which he uses or shall a portion of this cost be distributed (as by taxes) to the general public? In this connection, the general public must bear in mind that there is frequently an indirect value of the service which it alone receives; for example, the first transcontinental railroad in the United States made possible the development of the Western territories and the knitting together of widely separated populations into a homogeneous community. Lastly, there remains the relation between the character of the industrial activities and the requirement for good government. Will a given policy of industrial activity, if permitted, react on the political security of the community?

Ordinarily, competition and the relatively diminutive character of the individual industrial activity have been found to regulate satisfactorily the relations of the four interested parties mentioned. In the absence of competition, whether due to physical conditions or otherwise, and even in the presence of competition in the case of activities of great importance, some form of artificial regulation of the more or less conflicting interests of the various parties must be resorted to, or abuses will creep in and multiply to the point where dangerous unrest is created, as has been the case in several localities and on several occasions in the transportation industry of the United States.

4.—What Is Valuation and What Are Its Uses in Connection with Industrial Regulation?

The casual observer would be apt to say that valuation is the process of finding value. Such, however, is far from being the entire story.

Valuation is the process of ascertaining one or more of a number of things, among which the following may be mentioned as being the most prominent:

1.—Forced sale value—being the amount in dollars for which a property would sell if thrown on the market, as at sheriff sale.
2.—Market value—being the amount for which a property would sell when the owner is desirous, but not compelled to sell, and when the purchaser is desirous, but not compelled to purchase.
3.—Fair value—being the value for which the property would sell if the commodity rates were fair, if the owner was desirous, but not obliged to sell, and if the buyer was desirous, but not obliged to buy.
4.—Investment to date—being the net amount of capital which has been invested in the property to date, and, consequently, including expenditures for abandoned property and excluding the value of aids, gifts, grants, and donations received.
5.—Original cost to date—being the same as investment to date, except that the expenditure for abandoned property is excluded.
6.—Cost of reproduction—being the estimated cost, under normal conditions as of the date of valuation, of reproducing the existing property.
7.—Physical depreciation—being the percentage of the useful life of the existing property which has been consumed through age and use.
8.—Depreciation of obsolescence and inadequacy—being the percentage of the life of the property, as a whole and for its present uses, which has elapsed.
9.—Tax value—being the amount on which the property is taxed (and depending on the local tax laws).

The principal uses claimed for valuation in connection with industrial regulation are that the data are more or less necessary in order to arrive at equitable conclusions with reference to taxation, to individual rates, to the general rate level, to the amount to be paid in cases of condemnation and sale, to capitalization, and to the giving of needed information to the investor.

5.—What Is Value and How Many Kinds of Value Are There?

It is the fashion in certain circles to speak of value as being a nebulous sort of thing, undefinable and incomprehensible for valuation purposes. It is another example of the cuttle-fish instinct to muddy the water with which the subject of valuation is so frequently approached. The necessary first step in any logical consideration of the subject of valuation is to define clearly this term in its intended uses.

Definition.—Value is a ratio in exchange.

In other words, it is a statement of the number of units of one kind for which a single unit of another kind is exchangeable. It is a mere abstraction and requires the addition of an explanatory and limiting term to make it available for practical use. To illustrate, a diamond may have the same money or pecuniary value as fifty tons of coal, but it has not the heating value of one ton.

The forced-sale value of a property (which is usually adopted as the tax value) is often only half, or less, of the normal fair value where neither buyer nor seller act under compulsion. Also, there is the sentimental value which the owner may place on a commercially worthless heirloom.

Definition.—Pecuniary value is the amount of money for which a property will sell when the owner desires, but is not obliged to sell, and the purchaser desires, but is not obliged to buy.

In this discussion, unless specifically stated to the contrary, it is this value that is referred to whenever the term "value" is used.

Evidently (pecuniary) value, as defined, is determined solely by economic considerations.

Definition.—Market value is the value of a property as determined by present and probable future economic conditions.

Regardless of the fairness of the rates in effect in any property subject to regulation, market value is determined by the existence and probable continuance or discontinuance of these rates, and in disregard of their fairness except as this may reflect on their probable permanence.

Definition.—Fair value is the value which a property would have if, for the present rates, fair rates were substituted, with the reasonable certainty that they would continue in the future.

It is evident that there are as many values for a property as there are points of view from which the subject can be approached. For the

purpose of this discussion, value will be limited to that for rate regulation and for condemnation and sale.

6.—Profitableness Under Fair Rates, the Measure of Fair Value.

What is undoubtedly the fundamental economic law to be kept in mind in the valuation of property for condemnation or for rate regulation has been stated by the Supreme Court of the United States, in Cleveland, Cincinnati, Chicago and St. Louis Railway Company *vs.* Backus, 154 U. S. 439, in the following terms:

"But the value of the property results from the use to which it is put and varies with the profitableness of that use, present and prospective, actual and anticipated. There is no pecuniary value outside of that which results from such use. The amount and profitable character of such use determines the value. * * *"

Although it is true that, for a property not subject to regulation, the value at any given time is measured by the profitableness, present and prospective, actual and anticipated, this is not the value (more properly termed the fair value) to be found for use in condemnation or for use with reference to rate regulation. For such purpose, fair value is measured by profitableness, present and prospective, actual and anticipated, under fair rates. If this was not the case, it would be possible, through rate regulation, to reduce the rates and, consequently, the net earnings and the profitableness of the property to any point arbitrarily selected, and then obtain a value for condemnation purposes, based on such unfair rates, which would be far below the fair value of the property. Such a procedure would seem, equitably, to be inconceivable.

The Courts have called attention to the fact that, where the fairness of rates is in doubt, profitableness resulting from such rates cannot properly be used in the determination of fair value. This is axiomatic. The converse is also axiomatic, namely, that where the rates are acknowledged to be fair, the fair value can properly be ascertained by the use of the resulting profitableness as its measure.

As fair value is dependent on fair rates and fair rates on fair value, it would seem immaterial, when neither is known, which is to be ascertained first, except that, contrary to the general view, it is practically much more convenient first to ascertain fair rates and then therefrom to ascertain fair value, than to proceed in the opposite direction.

7.—"Cost" *vs.* Value.

When the fairness of the rates is questioned, it is impossible directly to apply any known variety of profitableness to the measurement of fair value; consequently, "cost" in some relation to the property must be used. A brief consideration of several special cases, however, clearly indicates that, in general, there is no necessary fixed relation between the cost of a property and either its market value or its fair value.*

If, therefore, cost is to be used in the determination of fair value, it is necessary that it be applied (1), under such special conditions as shall create a known relation between such cost and the fair value, and (2), where such established relation shall be equitable. Then, wherever such conditions can be simulated, one can properly utilize such variety of cost in the determination of fair value.

Except through occasional accidental coincidence, however, the only circumstances under which cost bears a fixed relation to value are those in which some one having the necessary power decrees that such commodity rates shall be charged that the resultant profitableness will establish this chosen relationship. This can be done in the case of a monopoly, but it is an impossibility in the case of two or more properties subject to competition.†

In order that the owner of a monopoly under regulation shall not be deprived of that protection against confiscation which is guaranteed by the Constitution, the next step is to inquire in what specific case, capable of being simulated under the above circumstances, it is equitable to enforce some relation between cost and value and as to just what this cost and this relation are. This is a problem in economics and economic principles only are involved.

---

* A plant for the manufacture of furniture is constructed in the wilderness at a cost of $100 000. No purchasers can be found for the product and the salvage value of the plant is only $1 000. Here the relation of cost to value is as 100 to 1. A similar plant is built at the same cost where labor and raw materials are plentiful and where the market is so good that the average profits are $18 000 per year. If capital is worth 6% per annum, the value of this plant is $300 000 and the relation of cost to value is as 1 to 3. Between these extremes lie all varieties of relations between cost and value.

† Consider two plants, A and B, in competition. Being in competition, they must adopt the same selling prices, or one would do all the business. Assume that the "cost" of A is $100 000 and that of B $200 000; also that, at the present selling prices, A's gross earnings are $6 000, and his net earnings are $4 000 per year, while B's gross is $9 000 and his net $5 000. Suppose it is decreed that the selling price shall be raised one-third in order that A's net shall become $6 000. Then B's net becomes $8 000. Capitalizing, at 6%, A's value becomes $\frac{6\,000}{0.06} = \$100\,000$ and equals his "cost", while B's value becomes $\frac{8\,000}{0.06} = \$133\,333$ as against a "cost" of $200 000. No selling price applied to both will give each the same ratio of cost to value.

The owner of every regulated enterprise is entitled to earn the same profit as the same amount of capital, intelligence, and industry would normally enable him to earn in the field of free and open competition.* Therefore, it becomes of fundamental importance to establish the principles under which commodity selling price is determined in the open field of free competition.

8.—The Principles Governing Free Competition—Their Application to Valuation of a Monopoly.

Let us suppose some community is served as to some commodity by a producer whom we will call briefly the A. and B. Company. This company has been in the field for years and has no competition. Local conditions do not prevent competition, and the commodity price is not limited by the public's ability to pay.

Certain capitalists, whom we will call the X. Y. Company, are looking for a favorable opportunity to make investment of their surplus capital. They, of course, have the range of the entire field of investment, regulated and unregulated, foreign and domestic, from which to choose; they will enter that field which, on investigation, gives promise of offering the greatest inducement as to profit, risk considered. Among others, the field occupied by the A. and B. Company comes under their consideration. Their decision as to whether or not to become competitors of the A. and B. Company will be governed by the answer which they accept to the following question:

"Considering the difficulty of establishing a new enterprise in competition with an old, established concern, will it be possible, within a reasonable period of time for such new concern to create a more than normally profitable business, considering the amount of capital which would have to be invested?"

As to the amount of capital necessary to be invested in the proposed new enterprise, the X. Y. Company realizes the following:

1.—Neither the amount of money which it was necessary for the A. and B. Company to invest in its plant, nor the profitableness of that enterprise, has any bearing on the situation.

* To deny this is to establish one of two conditions: If a greater return is allowed, the public is assessed a greater than normal charge for service rendered. If the right to earn at least this amount is denied, and it becomes known that such is the rule, capital cannot be enticed into the enterprise, and it will become dependent on Government ownership or will be destroyed. For it is an unquestionable fact that liquid capital is free and will be invested only where it can obtain at least the normal rate of return, risk considered. The entire field of investment in freely competitive enterprises, at home and abroad, is open to it at all times. It cannot be coerced into entering a regulated field where it will be compelled to accept less than the normal return obtainable in the competitive field.

2.—The X. Y. Company will be obliged to pay present-day prices for the land, labor, and material entering into the construction of its plant.

3.—The possible volume of business is limited in amount; also this total available must be divided with the A. and B. Company, already in the field.

4.—The A. and B. Company cannot secure commodity prices higher than those which the customer can afford to pay; the X. Y. Company cannot secure prices higher than those of the A. and B. Company.

5.—In determining the total amount of capital which the X. Y. Company must invest in its proposed enterprise, there must be included not only the actual expenditures for construction, but also the loss of a normal rate of return on its expenditures during the construction period and during the lean years (the "development period") which must follow, during which its volume of business is being built up to a sufficient density to enable the normal rate of return to be earned on the entire investment.

One of the most common causes of failure of business concerns is insufficient capital; the insufficiency is all too frequently caused by under-estimating the capital requirements of the development period and by failing to provide adequately for contingencies.

In determining the amount of capital necessary in the competition with the A. and B. Company, the X. Y. Company would ordinarily prepare its own plans, estimate the purchase price of the land prospectively required, and estimate the construction and operating costs of the prospective plant, etc., in addition to estimating the volume of business and the unit selling price probably obtainable.

As a matter of convenience, however, the X. Y. Company might conclude that it could obtain practically the same construction-cost and operating-cost figures by taking the estimated cost of reproduction of the A. and B. Company's plant under present-day conditions and by using the A. and B. Company's unit operating costs. Herein lies the sole economic justification for accepting "cost of reproduction" as a major element in the determination of value. The X. Y. Company would still be obliged, however, to make an independent estimate, not only of the amount of business which it, the X. Y. Company, as a competitor, could secure, but also of the capital cost to it of its develop-

ment period under these conditions; it could not substitute A. and B. Company data for this purpose and obtain acceptable results.

In the field of free competition, it is the conditions facing the prospective competitor and not the cost of the existing property which control commodity selling price and, consequently, profitableness and value of the latter. The value of any unregulated individual enterprise bears no necessary relation to its cost. For illustration: The cost of a manufacturing plant constructed in the heart of Alaska would be much greater than that of a duplicate plant constructed on a railroad in the State of New York; but the profitableness of the New York plant, and, consequently, its value, would probably be much greater than that of the Alaska plant.

Consideration of the preceding illustration of the working of competition in the regulation of commodity price indicates as follows:

A.—The fair commodity selling price at the time of investigation and in the field occupied by the A. and B. Company is that which is just sufficient to permit a prospective competitor—as the X. Y. Company—a normal rate of return, risk considered, on its necessary capital outlay, this being based on a development period not exceeding that reasonable time which capital would be content to wait for a fair return. For this is a free field, wide open to all competition; this commodity price neither invites competition nor repels it; a higher price established by the A. and B. Company would attract competition, while a lower price would repel it.

B.—The measure of fair value of the A. and B. Company is its profitableness, present and prospective, at this fair commodity selling price—just sufficient to permit a prospective competitor to earn a normal rate of return, risk considered, on its necessary capital outlay.

In valuation in the non-competitive fields, it is proper, therefore, instead of constructing a theoretical "reproduced property" as is sometimes suggested, to construct a theoretical "prospective competitor". Thereby the conditions governing commodity price in the competitive fields are simulated and the way is thus opened to estimate fair commodity price and fair value of the property under valuation.

It is to be noted that the illustration, and, consequently, the principles deduced therefrom, refer only to the case where the existing company has no competitor; in other words, it is a monopoly, though

able to remain so only by not charging unfair prices for its commodities.

9.—Method of Estimating the Fair Value of an Enterprise Subject to Competition.

Where the valuation of competitive properties is at issue, the same principles can be applied by first considering all the competitive properties as a single unit, such unit being, of course, a monopoly of the type used in the illustration. In this manner, through resort to the use of the prospective competitor for this monopoly, the fair commodity price and the sum of the fair values of all the competitors are obtained.

The problem still to be solved is, having estimated the sum of the fair profitableness and of the fair values of the properties regarded as a unit, and having records showing their present and past individual operating statistics, how to find their individual fair values.

The first step is to compare the sum of the fair profitableness with the sum of the normal actual profitableness and ascertain the percentage by which the actual must be raised or lowered to equal the fair profitableness. Next, apply this percentage as a correction to each individual normal actual profitableness in order to obtain its fair profitableness; from this, compute fair value by capitalizing at the normal rate of return, risk considered, in such industry. For example, three railroads—A, B, and C—are in competition in a certain district; they have present gross earnings of $10 000 000 and net earnings of $4 000 000, divided between them, as shown in Table 1.

TABLE 1.

Road. (1)	Actual gross. (2)	Actual net. (3)	Fair net. (4)	Fair value at 6 per cent. (5)
A	$2 000 000	$800 000	$1 000 000	$16 667 000
B	3 000 000	950 000	1 250 000	20 833 000
C	5 000 000	2 250 000	2 750 000	45 833 000
Total.....	$10 000 000	$4 000 000	$5 000 000	$83 333 000

Assume that valuation indicated that the total fair profitableness of the three railroads should be $5 000 000 instead of $4 000 000. In order to increase the net of $4 000 000 to $5 000 000, it will be necessary to

increase the gross earnings $1 000 000, or 10%, this being brought about by a 10% raise in the general rate level. Adding 10% of its gross earnings to the present net earnings of each railroad gives the fair net, as shown in Table 1, Column 4. This amount capitalized at 6% indicates a fair value, as shown in Column 5. If an individual rate, being too high, is lowered, this merely requires that slightly more than 10% be added to the other rates to produce the necessary fair gross earnings.

10.—Assumptions and Mode of Procedure in the Determination of the Fair Value of a Monopoly Railroad.

In devising the various assumptions which must be adopted, in the "competitor" method of estimating fair value, two fundamental facts should be kept constantly in view as a guide, namely:

1.—The object of the resort to the theoretical "prospective competitor" is to simulate, for the property under valuation, the condition which would normally be produced if that monopoly were actually subject to normal free competition, and thereby to make possible an estimate of what its profitableness, under such conditions, would be.

2.—It is evident that the entire economic justification for the use of cost of reproduction as one element in the determination of value lies in that, if properly used, it ordinarily gives practically the same results as would be obtained from an out-and-out new estimate of the cost of construction of a prospective competitive plant; the assumption must, consequently, always be made with this fact in view.

A.—Assumptions.—

Assumption 1.—The prospective competitor has the same accessibility to all sources of revenue as the property under valuation. In other words, it can, when properly seasoned, offer to the customers of the monopoly exactly the same facilities as those offered by the monopoly. To illustrate, the company under valuation has certain traffic agreements with its connections; the prospective competitor must be assumed, at the cost of a reasonable amount of negotiation, to secure the same terms. The old company reaches a great manufacturing plant by means of a track located through the only available route; the competitor must be assumed to be able to reach the same plant at "cost of reproduction" of the old company's track.

Assumption 2.—The development of the earning power of the competitor will occur through competition, under normal conditions, with the monopoly under valuation, for all the available business, present and prospective.

Inasmuch as the competitor, when properly seasoned, is able to offer the same inducements as can be offered by the property under valuation, it would ordinarily appear that, shortly after the commencement of its operation, the competitor should divide equally with the property under valuation the then business of the latter. Thereafter, the normal rate of growth of business in the industry, in recent years, is the rate of growth to be assumed for the business of the competitor, for the reason that one of the objects to be accomplished is the reduction of development cost to a normal basis regardless of the history of the individual enterprise (usually a history of small enterprises, failing, re-organized, combined, and re-combined over long periods of time).

Assumption 3.—The construction of the competitor's plant will be carried out under present-day methods, at present-day normal prices, and under present-day legal and economic conditions. The dates of construction of the individual pieces of property will be selected so as economically to harmonize with the needs indicated by the programme of development of its earning power.

Except as can clearly be shown would be carried out otherwise under the present-day conditions confronting the competitor, the physical characteristics, and, consequently, the construction quantities, including land, of the competitor are taken as ultimately identical with those of the monopoly under valuation. Construction evidently economically greatly in excess of requirements would be developed piecemeal as required. Thus, the competitor railroad would ultimately have the same length of line, grades, curvature, quantities of grading, etc., as the railroad under valuation, but the structure built of materials no longer available would be reproduced with accessible materials of equal suitability.

Assumption 4.—The naked land value of the lands adjacent to those required by the competitor will be the same, in each case, as the naked land value of the lands adjacent to those of the monopoly. The improvements assumed to be resting on the land required for the competitor are of the same character and value per acre as those on similar lands in the general vicinity, but not necessarily adjoining the monop-

oly's local facilities. The right of a competitor to use public streets would, or would not, be paid for, according as present-day practices in the community dictate.

Assumption 5.—The competitor will be obliged to pay for its land whatever amounts experience teaches would ordinarily have to be paid, in such communities, by railroads, for lands having naked land values equal to those surrounding the lands of the old company. These prices would include payments account severance and other damages.

B.—Mode of Procedure.—

1.—A programme showing in commodities, not in dollars, the estimated gross business of the competitor, year by year, will be developed for a period sufficiently long to equal, at its end, the normal business of the property under valuation, as of the date of valuation.

2.—A construction cost programme based, in general, on the reproduction of the existing properties of the monopoly under valuation, but at a rate and in an order harmonizing economically with the adopted traffic programme of the competitor, will next be made.

3.—An operating cost programme showing year by year the competitor's estimated gross operating costs, will next be constructed. There must be included in operating expenses a proper annual allowance for deterioration, obsolescence, abandoned property, maintenance, taxes, and rentals accruing after the commencement of operation; amounts accruing before this date are a proper addition to construction costs.

4.—Tables of annual gross and net earnings of the competitor should next be prepared. The rate level to be used in estimating the competitor's gross earnings is the lowest rate level which, within that reasonable time which capital would be contented to wait, will produce net earnings for the competitor equal to a fair return on the competitor's cost to date.

5.—From the preceding, the final table showing the competitor's estimated cost to date for each year and including loss of interest during construction and loss of fair return during operation can be prepared.

6.—Having found the proper general rate level for use in estimating the prospective competitor's gross earnings, the fair value of the property under valuation is obtained by capitalizing its profitableness at this same rate level.

II. General Discussion of Miscellaneous Subjects.

1. Summary of Important Principles Enunciated by the Courts with Reference to Fair Value and Fair Return.

The essential principles enunciated by the Courts with reference to fair value and fair return can be summarized as follows:

1.—What the company is entitled to ask in order that it may have just compensation, is a fair return on the fair or reasonable value of that which is at the time utilized for the public convenience.

2.—On the other hand, what the public is entitled to demand is that no more than a reasonable compensation shall be exacted for the service performed.

3.—The public does not underwrite unwise or improvident expenditures; such expenditures do not add to the fair or reasonable value of any property and the company cannot demand of the public that it be compensated for them.

We still are left by these decisions to discover the principles on which a proper method can be based for ascertaining (1), what is the fair value of the property of the company as used; and (2), what is a reasonable compensation for the service performed.

Nor does the following from San Diego Land and Town Company *vs.* Jasper, materially forward the investigation:

"The ascertainment of that value is not controlled by artificial rules. It is not a matter of formulas, but there must be a reasonable judgment having its basis in a proper consideration of all relevant facts. The scope of the inquiry was thus broadly described in Smyth *vs.* Ames, 'in order to ascertain that value, the original cost of construction, the amount expended in permanent improvements, the amount and market value of its bonds and stock, the present as compared with the original cost of construction, the probable earning capacity under particular rates prescribed by statute, and the sum required to meet operating expenses, are all matters for consideration, and are to be given such weight as may be just and right in each case. We do not say that there may not be other matters to be regarded in estimating the value of the property.'"

2.—That Reasonable Compensation to Which Rates Are to Be Limited.

Most enterprises under regulation differ from those operating in a free competitive field in that the former, to a greater or less extent, are

protected from competition by the interposition of various physical and legal barriers. Thus, a water-works may be protected from competition by legislative enactment, or it may be protected through ownership of the only reasonably available source of supply.

Reading between the lines of the Court decisions with reference to the fairness of individual cases of rate regulation, a broad guiding principle which seems to have been kept in mind is that the ruling should be such as to deprive the regulated enterprise of the benefits of any monopolistic protection and to permit of the earning only of such a return as, in the field of free and open competition, would ordinarily accrue to a similar expenditure of energy, foresight, and capital. This is well illustrated by the remark of Justice Holmes in Cedar Rapids Gas Company *vs.* Cedar Rapids, that what the Court excluded was good will or advantage incident to the possession of a monopoly so far as might be supposed to give the plaintiff the power to charge more than a reasonable price. The following may aid in illustration:

1. Assume that a certain farmer takes his wheat to Chicago and demands for it $3 per bushel. Is that an unreasonable price? No, not if he can get it, for this is a free, competitive market; if the circumstances did not justify the price, others would fill the demand at a lower price, compelling him also to lower his price or keep his wheat.

2. A certain community obtains its water supply from a lake 10 miles distant, hauling by wagon at a cost of $1 per 1 000 gal. The A. and B. Company builds a pipe line and delivers water to the town at a cost, including normal rate of profit, of 10 cents per 1 000 gal.; it charges 50 cents, making a very high return on the investment. The quantity of water consumed by the town is so small, however, that no rival entering the field and dividing the demand with the present company could furnish water profitably for less than 55 cents. Is the 50-cent rate unreasonable? No, because the business is freely competitive; as the demand increases, the company will be obliged to lower its rates to prevent competition. Meanwhile, the company, by its enterprise, is performing a public service by saving to the town 50 cents on each 1 000 gal. consumed as compared with the cost under the old method of haul.

3. Suppose that, in the preceding case, the A. and B. Company buys the water supply and thus renders competition difficult, as the next source of supply is 20 miles away. Because of the distance—20 miles—

and the small demand of the town, it would cost the X. Y. Company 80 cents per 1 000 gal. to deliver water at a normal profit. Would it be reasonable for the A. and B. Company to charge 75 cents under these circumstances? The charge would be unreasonable because it is now based, not on that which would be established if competition prevailed, but, on the contrary, on the holding of a monopoly of the water supply in the vicinity.

4. A railroad was built from the City of A into certain undeveloped coalfields at B; *en route* it passes through a gorge which furnishes the only low-grade line across the mountain between the two points. As it completely occupies the gorge, no other railroad can be built, except at a prohibitive cost, over the mountain. A transportation charge which would net 6% on the cost of any line over the mountain would pay 20% on the cost of the gorge route. Owing to the absence of other coalfields in the vicinity, coal could be moved at a profit even at this high charge. Would the charge under these conditions be unfair? The charge would be unfair because it is based on a monopoly of the gorge route, and not on rates which competition would establish in the absence of this physical barrier.

The frequently recurring statement in the older decisions that "a public service company cannot lawfully charge more than the services are reasonably worth to the public as individuals" becomes an absurdity if literally interpreted. Suppose, that, for example, the market for lumber on the A. and B. Railroad is at B and is $10 per 1 000 ft.; a farmer owns timber some miles from the railroad at A, its distance from the railroad being so great that the cost of cutting and hauling to the railroad is $10 per 1 000 ft., being just equal to the price which he would receive for the timber if delivered to the market at B. Inasmuch as there would be no profit to him in the transaction, the value to him of the service performed by the railroad company in hauling his timber from A to B would be nothing; consequently, under the literal interpretation of the decision, the railroad company could make no charge for the service, because it possessed no value to the owner of the shipment.

In the later decisions of the Courts, it has evidently been recognized that rates, to be fair, must be fair to both parties to the transaction, and that the statement as to the value of the service is meaningless; it is consequently omitted. Thus, in Darnell *vs.* Edwards, 244 U. S.

564, the Court, while pointing out that the public should not be compelled to pay rates based on extravagant expenditures, states: "In determining whether rates are confiscatory, because not yielding a proper return, the basis of calculation is the fair value of the property used in the service of the public."

3.—The Fair Value of a Property Subject to Rate Regulation Is the Same for Condemnation as for Rate Regulation.

The well-known principle of law to be observed in condemnation cases is that the fair price to be paid the owner is that on which a buyer, desiring but not compelled to buy, would agree with a seller, desiring but not compelled to sell. The basis of agreement between the buyer and the seller, in such cases, is a conscious or unconscious meeting of their minds as to the profitableness, present and prospective, actual and anticipated, of the property under discussion and a translation of this into terms of value.

Where the property is subject to rate regulation and where, therefore, the profitableness can be varied by regulating the rates, it is evident that this rule must be modified so that it calls for a meeting of the minds of the prospective buyer and the prospective seller, based on their views of profitableness under fair rates.

In case of rate regulation, the owner is entitled to such rates as will enable him to earn a fair return on the fair value of his property. The measure of the fair value of his property is evidently the profitableness under fair rates, but this is identical with the fair value as determined by the previously mentioned rule to be observed in condemnation where rate regulation is in effect.

It is assumed, of course, that the same property is the subject of consideration in each case and that, if only the portion of the property used for carrier purposes is considered for rate regulation, the same (and not also all the non-carrier property) will be the subject of consideration for condemnation.

4.—The General Rate Level (and not Individual Rates) Is the Subject of the Inquiry in the Determination of Fair Value of a Railway Property.

The movement of bituminous coal to the Lake ports furnishes an excellent illustration of the situation to be dealt with in the consid-

eration of individual rates. Coals for the Lake ports are obtained from the coalfields of Ohio, Indiana, Illinois, West Virginia, and Kentucky. The length of haul varies from a few miles to several hundred miles; also, the cost of transportation per ton-mile varies because of variations in grades, size of engine, etc. The quality of the coal, and, consequently, the selling price at the Lake port, varies with the different fields. The cost of production of the coal at the mines varies because of differences in rate of pay of the miners, thickness of vein, relative quantity of slate, etc. A uniform rate per ton-mile would drive some of the more distant fields out of the market. The situation resolves itself into this, that, with a fixed coal selling price per ton at the Lake port, the profit on the total operation involved is to be divided between the owner of the coal, the coal miner, the coal operator, the transporter, and the distributor, on some equitable basis.

It is evident that the position taken by so many of those engaged in the regulation of rates, to the effect that the fair value of the property used is not the principal factor and is often not even an important factor in the determination of fair rates, is entirely correct when limited to the consideration of individual rates. For the purpose of obtaining the fair value of the property used for the public, fair profitableness is the only true measure of such fair value. Fair profitableness, however, in turn depends on, not the fairness of the individual rate, but the fairness of the general rate level. In such valuation work, it can be assumed that all the individual rates are equally fair, or unfair, to the carrier and that, consequently, the raising or lowering of the average rate level by an uniform percentage, is the remedy for unfairness, if such exists. The fairness, or unfairness, of the average rate level is determined by the one consideration that it will, or will not, afford a fair return on the fair value of the property used for the public.

Fair value, therefore, becomes an indispensable factor in the determination of the fairness of the general rate level.

5.—The Relation of Risk to Rate of Return.

Liquid capital, in its choice of a field of investment, cannot be coerced; the direction of its movement is controlled solely by economic conditions. Provided it is merely a risk and not the certainty of loss, capital in seeking investment is not primarily concerned at the pres-

ence of risk, for it is able to protect itself by varying the rate of premium demanded.

No man makes his individual investment on any other basis than the hope that his particular investment is to be numbered among the successful ones. Many prove unsuccessful, however, and these failures, becoming more or less known, produce fear, great or little, according to their ratio to the successes. This fear must be overbalanced by the offer of a premium over safe investment rate. This premium is in the form of the known high profit made by the successes. If the premium does not appear to be high enough, the investor goes elsewhere.

In order that capital shall continue to enter a given industry, it is necessary that the return, risk considered, on capital invested in the industry as a whole must equal the return from investment in other industries. This is a matter of fundamental economic law and is not permanently susceptible of modification by Court or Commission.

Suppose that, from the beginning, a single capitalist had furnished all the capital for each and every individual enterprise in a given industry; one in ten of his investments, measured by the amount of capital invested, proved failures, and the capital invested therein has been destroyed; the remainder are still live enterprises producing various degrees of return (or even loss) on the investment. In order that the capitalist shall be as well off to-day as if he had simply deposited his capital in a savings bank at 3% interest, he must have received from the successful industries a return on his total investment equal to 3% per year plus the amount of capital destroyed to date. Stated differently, he must have received each year on the total capital invested in still living enterprises a rate equal to the rate of return on safe investment plus the annual rate of destruction of capital in the industry.

If regulation holds the rate below this economic level, it may be possible for a time to entice unwary investors into the industry; sooner or later, however, its rate of development will be retarded if not destroyed. To hasten development, rates must be above normal. If the risks of the industry vary in different sections of the country, the rate of return will likewise have to vary, or those sections where the risk is greatest will suffer.

6.—How Can the Fair Rate of Return on the Fair Value of Property be Ascertained?

Most railroad property is owned by corporations the securities of which are more or less actively traded in on the stock exchanges of the country; consequently, the current prices can be ascertained with little difficulty. Also, the records of the corporation show the amount of such securities outstanding from time to time in the hands of the public. The current prices multiplied by the amount outstanding give the public's opinion from time to time as to the market value of such property. The net earnings of the property from time to time are also ascertainable from the records of the corporation. Both the net earnings and the public's opinion as to market value are constantly fluctuating, but if we take average figures for each over a considerable period of time and divide the average net earnings (profitableness) by the average market value, the result will closely approximate the rate of return which, risk considered, the public demands on railroad securities before it will invest in them.

7.—General Observations on the Valuation of Properties Subject to Competition.

The presence of competitors greatly complicates the problem of valuation, for the reason that there are, in such cases, many intangible factors which affect profitableness and which cannot properly be overlooked. For example, suppose all the railroads in a certain self-contained district were owned and operated as a single property. The methods suggested for the valuation of a monopoly could readily be applied. Suppose, however, this single railway system is split up into several more or less competing systems under different ownership and operation. It still holds true that profitableness under fair rates is the measure of fair value in each individual case; but how shall we compute this profitableness?

In the case of a railroad forming a part of a group in which the lines are in competition, one with the other, some of the elements which affect profitableness are:

Affecting Number of Units of Output.—

Length of road;

Density and character of adjacent population;

Number and character of industries adjacent;
Traffic production or absorption capacity of connections;
Traffic capacity of the railroad—number of main tracks, character and size of terminals, number, character, and size of available equipment, etc.

Affecting Unit Price of Output.—

Rate regulation;
Length of haul;
Character of product transported;
Intensity of competition;
Percentage of through rate secured, etc.

Affecting Unit Cost of Output.—

Maximum grades and curvature;
Length of haul;
Character of product;
Character of equipment;
Adequacy of facilities;
Density of traffic;
Character of agreement affecting interchange of traffic, etc.;
Regulations affecting quality of service, etc.

Miscellaneous.—It is usually customary to enumerate among the things which make profitableness possible:

The presence of the physical property;
The possession of a franchise permitting of the operation of such property;
The fact that the period has already been passed through during which occurs the development of business to the point where its volume is sufficient for fair profitableness (this is usually called "going concern value");
The fact that the property has been constructed so as to permit of unity of use and connected operation instead of being constructed so that it cannot be so used or operated;
The fact that the management has created friends who become the customers and thus the source of revenue of the property.

Remembering that value is measured by profitableness, the value to an individual railroad of the possession by such railroad of the various elements of profitableness (and, therefore, of value) is measured, in the case of each such element, by the effect produced by the presence of such element on the total profitableness of the railroad. These various elements can affect the profitableness of the railroad as a whole only by increasing earnings, or by reducing expenses, or both. In order, therefore, to compute value in this manner, it is necessary to compute separately for each element of value of the property, its effect on earnings and expenses (and, consequently, on profitableness).

To attempt thus to compute value by separately computing what part of the total value inheres in each of the various elements of value previously enumerated (and the many others which are suggested by such enumeration) is evidently to become involved in a hopeless mass of detail from which useful results cannot emerge. It would be useless to attempt to compute the value of a few of these elements unless the value of the sum of the remainder is known.

The composite effect of all the various elements of value possessed by the individual railroad property is accurately weighed and registered in the profitableness resulting from operation under the existing conditions. This, however, merely gives market value and not necessarily fair value (which would be measured by profitableness, present and prospective, under fair commodity rates). How then shall we proceed to estimate fair value?

One suggestion advanced is that, in such case, fair value equals cost plus "other values and elements of value". The only true measure of value is profitableness. The profitableness of an individual railroad, subject to competition, bears no necessary relation, and can be made to bear no fixed relation, to cost. Therefore, to state that the value of such a property is equal to its "cost" plus "other values and elements of value" does not in any way advance the process of computing such value. It is merely equivalent to stating that the weight of a steer equals 500 lb. plus certain other weights yet to be ascertained.

8.—The Relation of Depreciation and of Appreciation to Fair Value.

Depreciation is a lessening in value as compared with value under the basic condition (called "new"); depreciation is brought about by any cause which reduces profitableness, present or prospective. Appre-

ciation is the opposite of depreciation; it may be regarded as negative depreciation.

Solidification of roadbed, grassing of slopes, etc., adjustment of working parts of machinery, etc., reduce future maintenance costs; development of traffic increases net earnings; both, therefore, add to the profitableness and thus produce appreciation in value.

Physical deterioration, obsolescence, and inadequacy affect profitableness by, at some future time, increasing gross expenses as compared with the gross expenses necessary in the absence of such conditions and so produce depreciation in value. The usual remedial process is the replacement of certain portions of the original property at the cost of the expenditure involved in restoring original conditions. This expenditure is usually termed "maintenance cost". Under certain conditions, this cost matures at regular intervals in amounts which are not embarrassing. Under other conditions, the increased cost accrues over long periods of time until, at maturity, it assumes proportions which may produce disastrous results in three ways, namely:

The treasury of the enterprise may suddenly be called on for large sums which it may not be in a position readily to supply and which, therefore, might involve the enterprise in financial difficulties.

This gradual accrual may not become apparent in the ordinary annual reports of the corporation to its stockholders. These stockholders, as well as intending stockholders, basing their estimates of value of the property on the reported past net earnings, form an entirely erroneous conclusion, because they do not realize that the future earning power will be much diminished when it becomes necessary to make the renewals required on account of the heavy accruals of deterioration.

If the commodity rates are under regulation and subject to frequent adjustment, the fluctuations of earning power brought about by gradual accrual and sudden maturity of deterioration, cause an unequal distribution of the production cost among early and late purchasers of the product.

For these reasons it has become customary, from time to time, to include in operating expenses an amount for "depreciation", more or less approximating the annual accrual. These amounts of "depreciation" are included in current operating expenses and a book credit is set up, against which credit the actual expenditures to remove matured

deterioration are charged as they occur. Sometimes, in addition to the mere bookkeeping, an actual fund is created, segregating the amount charged to "depreciation" from the other gross earnings of the corporations, thus establishing a more complete protection.

Various methods have been proposed for estimating the amount of accrual of deterioration, which approximate more or less closely to the actual accrual. The object in each case is the same, namely, to distribute maintenance cost more uniformly than if only expenditures for replacement of matured deterioration were charged thereto.

It is evident that the item which is a final charge to maintenance expense is the cost of removal of deterioration (or "depreciation") and not the deterioration itself, which latter is a condition and not an expense.

In the absence of removal, the present worth of the future cost of such removal is evidently the measure of the depreciation in value as compared with the value if the removal had already been completed, all other conditions remaining unaltered. It is to be observed that, in properties made up of great numbers of articles, as the ties in a railroad track, there is a constant tendency of the amount of deterioration —of the loss of useful life—to reach 50% and to remain constant at that level. Such deterioration in the property as a whole never is removed—the property is designed so as to be really in normal use-condition only when this status is reached—and there is, consequently, no future cost of removal to consider and of which to compute the present worth.

In the case of appreciation, removal thereof is neither necessary nor desirable; nevertheless, the production of the appreciation, whether voluntarily or involuntarily, has usually been accompanied, in some form, by cost; this cost is either chargeable to maintenance or operating expenses, or it must be regarded as a capital expense incurred in the building up of the property to its present condition. As a matter of fact, the cost of that appreciation which takes the form of solidification of roadbed and ballast, grassing of right of way, adjustment of working parts of machinery, etc., ordinarily enters into operating expenses in railroad accounting and can be segregated only with difficulty, if at all, from the other items of operating expense, making it difficult to treat as a capital expense item.

Under the "competitor" method suggested for finding the value of a property, the first step is to estimate that fair rate level which, within that reasonable time which capital would be willing to wait, will produce net earnings for the competitor equal to a fair return on the competitor's cost to date. In order to determine this rate level, it is necessary to estimate, over a period of years, the gross and net earnings of the competitor. Whatever method of computing "depreciation" is in use on the property under valuation, should be applied to the estimation of the maintenance cost of the competitor during the period of years used for the determination of the fair rate level. Having in this manner determined the fair rate level, the next step is to estimate the profitableness, present and prospective, under the application of such rate level, of the property under valuation; this involves the estimating of the gross and net earnings, under such rate level, of the property under valuation. Here, again, the same rules with regard to the computation of "depreciation" should be applied to the estimation of operating expenses during such period, bearing in mind, also, the physical condition of the property and the probable desirability of increasing or decreasing the normal "depreciation" rate on account of such physical condition.

Attention is called to the fact that it is not directly the physical condition of the property which affects its value but, on the contrary, it is the effect of such physical condition on present and future operating expenses which influences value. It is probable that, under the valuation method proposed, it does not seriously modify the result whichever of the various "depreciation" rules is adopted in the computation, provided the rule is sufficiently accurate to produce, in the long run, a close approximation to actual maintenance expenditures and not, on the contrary, gradually pile up a considerable surplus or deficit.

9.—The Relation of Abandoned Property to Fair Value.

As it is the value of the property at present used for corporate purposes which is to be obtained, and as the value of such property is entirely independent of the amount of the property abandoned, it is evident that such abandoned property is to be ignored in arriving at fair value.

However, if the abandonment resulted from unavoidable causes, such as normal obsolescence, etc., the relation between the cost of the

property abandoned and the cost of the remaining property still in use is of interest, because of the light it throws on what is a fair rate of return in the industry in question. Fair rate of return is made up of two factors, rate of return in the absence of risk, and insurance premium to cover risk. The relation between abandoned property and the total property furnishes an indication of the degree of risk. Also, the subject is of considerable interest in connection with the establishment of rules governing the application of depreciation.

It may be well here to remark that it is only the value of the remaining useful life which is abandoned and that, in practice, this is generally reduced to a minimum by neglecting repairs for some time previous to abandonment and while still keeping the property in service.

10.—The Relation of Aids, Gifts, Grants, and Donations to Fair Value.

In practically all cases, the object of gifts, grants, etc., in whatever form these have been made, has been to induce capital to undertake an adventure in which the risk was otherwise prohibitively high. This additional inducement was really in the nature of a capitalized payment of an extraordinary insurance premium.

If, in valuation for the purpose of determining fair return, the value of the gifts should be excluded, then the effect of the gift is merely to put the giver in the position of being a silent partner in the business without in any way reducing the risk of the other partners; yet this reduction of risk was the primary object of the gift.

For example: The estimated cost of a project is $10 000 000, and it is further estimated that, under the commodity rates which must be used, the profitableness of the enterprise will not be more than $400 000, and may be less. As it is impossible to interest capital in an uncertainty with a maximum return of only 4%, certain outside parties, expecting great indirect benefit from the development of the industry, donate $5 000 000 to the corporation formed therefor. This means that the stockholders will be obliged to contribute only $5 000 000 instead of $10 000 000, while the plant which they will own will have cost $10 000 000 to produce. On the assumption that they will be permitted to have the entire return from the $10 000 000 investment, the probable return on the stockholders' investment of $5 000 000, therefore, become 8 per cent. If, on the contrary, the industry is to be subject to regulation and, because of the $5 000 000 donation, the rates

are to be cut to the point where only $200 000 is allowed to be earned, it is evident that the stockholders have not been benefited in any way by the donation, for their risk has not been reduced in intensity and they are still limited to a prospective maximum of 4% on their investment.

Under the method of valuation suggested, it is evidently of no concern to the prospective competitor whether the existing enterprise bought, begged, or stole its now owned property. It is the cost of developing and operating the competitor's plant which must determine the rate necessary to enable it to compete. Fair value of the property under valuation will be determined by its profitableness at this rate.

11.—The Relation of Property Owned but not Used by the Owner in the Public Service, to Fair Value.

It is self-evident that such property should not be included in the value on which fair return is to be allowed. It is to be regarded merely as an investment in which the public has no interest, and any returns from which should be excluded from operating revenue.

It is frequently necessary, however, especially in rapidly growing communities, to look well ahead of the present needs. This sometimes raises the question whether the property is or is not properly to be included in the valuation.

12.—The Relation of Property Used but not Owned to Fair Value.

The value of such property to the user is reflected in the net earnings directly and indirectly accruing from such use. Ordinarily, the gross earnings from such a property are included with the gross earnings from other properties in such manner as to make segregation practically impossible. Under such circumstances, the simplest method of handling for valuation purposes is to include in operating expenses the rental of such property, excluding the item entirely from the reproduction inventory; in some special cases it may be necessary to consider whether or not the terms of the rental are fair, or whether they represent unwise and improvident management, the results from which the public does not subscribe to.

Where it is possible to segregate from other sources of revenue the earnings accruing from the rental of a property not owned but used in the public service, and where the property bears a sufficiently impor-

tant relation to the remainder of the property under valuation, then it can be valued in the same manner as if owned and used. In this case, however, the rental must be excluded from consideration as earnings.

13.—The Relation of Property Owned and Used Jointly to Fair Value.

Recalling that the only true measure of value is profitableness, it is evident that the value to each of the users of a property utilized jointly is measured by the profitableness (gross earnings less gross expenses) accruing to the user from such property, regardless of the terms of ownership. Ordinarily, as the gross earnings accruing directly and indirectly from the use of such a property cannot be segregated from those accruing from other sources, the simplest method of valuation is to include in the gross expenses of each owner its proportion of the expenditures incurred on account of such use. The reproduction cost of the property is pro-rated to the different owners on this or other equitable percentage basis. Where the jointly used property is separately operated and the terms of ownership include the basis of distribution of profit or loss from such operation, the valuation of the jointly used property can be made independently and pro-rated to the users on the basis of the contract basis of distribution of profitableness.

14.—When Does "Construction" End and "Operation" Begin?

In the determination of the competitor's investment to date and the commodity price necessary to the securing of a fair return thereon, a clear understanding of the physical and accounting procedures involved is necessary.

The construction and development of a railroad property to the point where it is a paying going concern involve the following steps: First, the inception of the project and such preliminary promotion and financing as will permit of general investigation and incorporation of the project; second, the securing of sufficient capital to enable the preliminary and location surveys to be made and construction to be commenced. In most cases the purchase of right of way must slightly precede, locally, the commencement of construction. With the continuance of construction, additional capital must be secured. Finally, the point is reached where trains hauling passengers and freight are run, thus enabling capital to be secured from the sale of transportation as well as from the issuance of stocks and bonds.

With the beginning of construction, the processes of solidification, seasoning, and deterioration commence, and these processes increase in rapidity of action with the commencement of train service, thus necessitating expenditures for maintenance of the property already created; embankments settle and are partly destroyed through the action of the elements; grasses, etc., begin to cover the exposed surfaces; decay and wear begin to produce the necessity for later replacement. Meanwhile, construction continues; expenditures for operation and maintenance increase, and the density of train service and of traffic increases.

A time finally comes when it is arbitrarily stated that construction has been completed and that operation of the property has commenced. The failure to recognize that this dividing line is an absolutely arbitrary one, adopted merely for the purpose of facilitating organization matters, including the application of certain accounting rules, and having no relation whatever either to the cost or to the value of the property, leads to confusion in connection with valuation. The continuance of construction which, on ordinary railroads, never actually comes to a state of completion, is now called "additions and betterments"; in some cases it is called "maintenance". In ordinary accounting rules, there is considered to be a great distinction between construction, additions and betterments, operation and maintenance, and "depreciation". For valuation purposes much confusion is avoided if all these terms are entirely disregarded and if, in their stead, the receipts and expenditures necessary to the full development of the property are directly considered without first subjecting them to such misleading classification. In this way the arbitrarily established dividing line between receipts, depending on their sources, and between costs, depending on the instruments used in producing the same, is made unnecessary.

15.—As of What Date Should the Valuation be Made, and What Are "Normal Prices" as of the Date of Valuation?

For practical use, the fair value of a property which must be used is that as of the date or period of use. Thus, for use in condemnation, it must be the fair value of the property as of the date of condemnation.

For use in the regulation of rates, it is necessary to bear in mind that it is undesirable to make frequent modification of rates, but that, on the contrary, they should be determined so as to be fair, on the

average, over a considerable period of time. This necessitates the drawing of conclusions as to the probable average conditions as to prices, etc., which will exist during such future period. The unit prices most satisfactory to be used for valuation for such purpose are those which, it is considered, will probably be a fair average of the prices over such future period. The only method of estimating probable future conditions is through the study of the past conditions; therefore, the ascertainment of average unit prices year by year over a considerable period of the past is necessary. In determining the average unit price for a given period of the past, actual sales furnish the basis. Inasmuch as these sales vary greatly in quantity, it is necessary that the average used be a weighted average and not merely an arithmetical average.

Normal price as of a given date may be defined as being the market price as of that date, assuming business conditions to be normal and not under the influence of undue optimism or pessimism as to the future.

16.—How can Valuation be Kept up to Date for Rate Regulation Purposes?

It must be borne in mind that valuation is not and cannot be made an exact science; neither is there any practical necessity that it should be so. The true measure of the value of a property, as has already been stated several times, is its profitableness, present and prospective, actual and anticipated. Evidently, prospective and anticipated profitableness in themselves can be estimated only approximately, and yet, in nearly all commercial transactions, it is the future prospect rather than the present fact which determines the investor's conclusions as to present value.

Having determined, with such reasonable accuracy as may be, the present value of a piece of property (future prospects being one of the vital considerations), the most important factors which, in the future, will bring about a modification of such estimated value are the appreciation and depreciation in the value of land owned or used, like fluctuation in the prices of labor and material such as have already entered in the construction of the property; the invention of improved methods of construction; additions and betterments necessary to the growth of the business will add quantities to those existing as of the date of valua-

tion; and property abandoned on account of obsolescence, etc., will reduce the valuation quantities. All these changes over a reasonable period of years, together with their effect on the future profitableness of the property, are considered in arriving at the original valuation; further, it is greatly to the interest of the public to avoid frequent fluctuations in commodity prices (freight and passenger rates, etc.). Presumably, therefore, the fair rates established at the time of the valuation (which rates are based, not on the conditions as of the instant of valuation only, but on prospective conditions as well) will be fair for a considerable period of time thereafter. Fluctuations due to additions and betterments and to abandoned property can be taken care of with considerable accuracy by the application of ordinary accounting methods. Variation in the fair value due to fluctuation in unit prices of labor and material can probably only be dealt with either by a new valuation from time to time, or by the keeping of a suitable index number such as that maintained by Bradstreet's, the *London Economist*, and others, but adopting a base arranged to represent the more important kinds of labor and material used in railway construction in their proper proportions, and using the fluctuations of this index for the purpose, from time to time, of applying percentage corrections to the original fair value. Fluctuations in land value could probably only be allowed for through the occasional making of reappraisals of selected properties and through the application of a percentage correction to all the land values.

A percentage correction applied in such manner to the original valuation, although crude, would still probably greatly extend the period of serviceability of the original valuation.

17.—Comparison of the Cost-of-Reproduction Method with the Prospective Competitor Method of Valuation.

1.—Land Values.—The Competitor Method assumes that, in the construction of its property, the competitor will be obliged to purchase land having the same present ordinary values and being subdivided in the same manner as similar lands adjoining the property under valuation as of the date of valuation. This avoids the absurdity, pointed out by Justice Hughes in the Minnesota Rate Case, of assuming that the railroad producing much of the value of the land is non-existent, but that the land retains its full value. Presumably, it might be

claimed that the competitor, in entering a town, would select a location for its line and for its terminals which would cost less per acre than the lands adjoining the property under valuation. The answer is that it is fair to presume that the original railroad located its line in such manner as to make the cost of land plus the cost of grading and other improvements a minimum, considering the value of the location with reference to convenience of access for traffic. The adoption of a different location would mean different grading quantities and also the estimating in terms of earning power of the difference of attractiveness of the two locations. This would involve such excessive complications as to make the problem practically unsolvable. The fair presumption is that the original line secured the best available location, cost considered, and that any other location would cost more or would be worth at least proportionally less. In practical operation and in results obtained, the two methods are identical, as to land. The competitor method is logical whereas the other is not.

2.—Present or Past Conditions.—By the competitor method, all questions as to whether present or past conditions apply in making the estimate are solved without difficulty. The reproduction theory affords no positive clue as to whether present or past conditions should be considered in individual cases, and there is much present controversy over this point.

3.—Construction Period.—The reproduction theory involves the reproduction of the property, as it is to-day, in one operation; thus, a four-track railroad would be reproduced as such absolutely regardless of the fact that no railroad, either the original occupant of the territory or a later competitor, ever is built in such a manner. The competitor theory calls for a gradual construction and development of the competitor at a rate dependent on rate of growth of traffic in the community and, therefore, is consistent with the invariable facts of such industrial development.

4.—Going Concern Value, and Cost of Development of Earning Power.—The reproduction theory admittedly carries the process of estimating value only to the point where the property has prepared to become a going concern but has not taken that step. This leaves an element of value called by the Courts "going concern value" to be ascertained by some succeeding process. No process departing greatly from clairvoyance has yet been devised. The competitor theory pro-

vides for the estimating of the cost of the development of the traffic on a basis readily applied in practice and governed by the application of simple principles to easily ascertainable facts.

III. A Study of the Virginian Railway.

In 1902, the construction of what is now the Virginian Railway was actively commenced by the late Mr. H. H. Rogers, the primary purpose being the economical transport of bituminous coal in great volume to the seaboard. The work was pushed as rapidly as financial conditions would permit. Covering the number of years that it did, the rapid completion of course was interfered with by various periods of business depression. The property is one of the few railroads in the United States which has been conceived and developed as an independent enterprise, most of the present railroad systems having been developed as separate entities and gradually combined. The statistics of this railroad, consequently, are of unusual interest for the purpose of illuminating the various problems connected with the ascertaining of the value of railroad properties.

Operation was commenced on the Virginian Railway in 1910, eight years after the commencement of construction. Thereafter, expenditures for construction (usually termed additions and betterments) were, in the main, for providing the additional facilities required to handle the rapidly developing business. The records of the company, partly owing to the fact that practically all the financing was done by Mr. Rogers himself, do not disclose the amount of capital invested in the enterprise as interest. It will be assumed, therefore, that sufficient capital for the ensuing 12 months was secured at the beginning of each such period and that 6% compounded annually had to be paid thereon. With this assumption, Table 2 gives the essential financial history of the Virginian Railway from its inception in 1902 to June 30th, 1916, and also shows what this history would have been had the rate level been 8% higher than it actually was.

For purpose of illustration, assume that to-day as compared with the period 1902-16:

(1).—There has been no change in construction methods or in unit prices of labor and material or in land values. Assume, further,

(2).—That the history of the Virginian Railway has been unaffected by the presence of competitors.

(3).—That the construction of the Virginian Railway and its traffic development proceeded at a normal pace.

(4).—That its physical condition was normal, that is, there was no matured deterioration, throughout its history.

(5).—That the rate level throughout the history of the property was fair.

Under such assumptions there would probably be few who would question that, as of the date of valuation, the fair value of such a property is measured by its cost to date—in this case, $69 522 883—as of June 30th, 1916.

Taking up the various assumptions and assuming that 6% is the fair rate of return on the fair value of such a property, the following considerations suggest themselves:

1.—Six per cent. on $69 522 883 is $4 171 373, whereas the net earnings for 1916 are $3 331 957. Evidently, on that date, the property was not earning a fair return on its cost. If the rate level throughout the history of the property had been 8% higher than it actually was, then the cost to date would have been $65 996 540; 6% on this amount is $3 959 792 and the net earnings for 1916 would have been $3 923 187, indicating that, based on these considerations alone, the rate level was about 8% too low throughout the history of the property and that, for this reason, the property to the end of 1916 has cost $3 526 343 more than it would have if the higher rate level had been in effect. Had the higher rates been in effect, the public, during the period, would have paid $2 877 237 more for transportation than it did.

Question A.—Should this increased cost equitably fall on the owners of the railroad through the assumption of the lower figure or should it fall on the public through the assumption of the higher figure as being the fair value of the property as of June 30th, 1916, under the above assumptions?

2.—Assume that the earning power of the property had developed more rapidly, so that, in 1914, the net earnings had been equal to the actual net earnings of 1916. This would have required a corresponding acceleration in the additions and betterments, and the cost to date as of June 30th, 1914, would have been $63 632 623 for a property identical in

every way with the actual property as of June 30th, 1916, which actual property cost $69 522 883, a difference of $5 890 260. On this new basis of development of earning power, the rates were about 5% too low to give a 6% return on the cost to date of the property as of June 30th, 1914, whereas they were 8% too low to give a 6% return on the identical property with the development period two years longer.

Question B.—Should this excess cost be borne by the public through its inclusion in fair value as of a given date, or should it be borne by the owners of the property through its exclusion?

Question C.—If the owners of the property should be penalized for their bad judgment in commencing the enterprise in advance of the normal public need, thereby adding to its cost, should they also be rewarded if they delay the carrying out of the project until the public need becomes abnormally acute, thus reducing the cost of the project? If bad judgment is penalized and good judgment not rewarded, what will become of the industry—collapse, or Government ownership?

Question D.—How shall it be determined whether or not the inception of the enterprise was in advance of the normal public need?

3.—Going back to the first case—that of the actual history of the Virginian Railway—suppose the date of valuation had been taken as of June 30th, 1914, instead of June 30th, 1916. In that case the cost to date of the property would have been $63 149 009; 6% on this amount is $3 788 940, whereas the actual net earnings for that year were only $2 641 048.

If the rate level had been 9% higher than it was, the cost to date would have been $62 884 206; 6% on this amount is $3 773 052 as against net earnings at the new rate level of $3 718 861 indicating that, under such conditions, and not considering the future, the rate level was slightly more than 9% too low as against an 8% deficit if the year 1916 had been adopted as the basis of calculation.

Question E.—In 1910 (the year in which the Virginian Railway was opened for operation), in determining the rate level to be used in the future on this property (on the assumption that it was not subject to competition) should this rate level have been based on the estimate that in 1914 it would give a fair return on the cost to date, or should it have been based on the fair return being reached in 1916, or in some other year? What considerations should determine the year to be selected?

Question F.—The coal traffic of the Virginian Railway is in competition to tide-water with the coal traffic of the Chesapeake and Ohio and of the Norfolk and Western Railways. If it is assumed that the actual rate level (which was 8% too low to give a 6% return on the cost to date of the Virginian Railway, as of June 30th, 1916) was just sufficient to give a 6% return on the cost to date of the Chesapeake and Ohio and of the Norfolk and Western Railways, would this fact have any bearing on the fair value of the Virginian Railway?

Question G.—Since the inception of the Virginian Railway, there has been an increase in unit prices of labor and material used in construction and operation and in the price of land along the railroad right of way. Do these facts have any bearing on the fair value of the Virginian Railway?

Question H.—If it is assumed that, for several years just prior to the date of valuation, the Virginian Railway had either been parsimonious or excessively liberal in the renewal of its rail, ties, and other materials, would this fact (which certainly would affect the operating expenses of the immediately succeeding years) have any bearing on its fair value as of the date of valuation?

It is the study of such considerations as those mentioned in the preceding paragraphs which has led very commonly to the conclusion stated elsewhere, that there is no general relation existing between the cost and the fair value of a property. It is evident that, if cost is to be used in the determination of fair value, it must be used only under such special circumstances as permit the relation between cost and value to be known.

The object of the Prospective Competitor Method of valuation is to ascertain the character of these special conditions and the relation which, under such conditions, exists between cost and value.

Applying to the Virginian Railway the Prospective Competitor Method of valuation, still assuming—for the purpose of illustration and because the data are lacking—that the value of the property is unaffected by the presence of competitors and that, since its inception, there has been no change in unit prices of labor and material, in land values, or in engineering methods:

1.—Under the assumption that the original construction proceeded at a normal pace, it is to be assumed of course that the construction of

the competitor to the beginning of operation will duplicate the historic construction to the same period.

2.—It will be assumed that the business handled by the competitor during the second year of its operation equals one-half that of the Virginian Railway as of the date of valuation. This provides one year of minor operation during which the roadbed is solidifying sufficiently for the normal handling of traffic.

3.—For the reason that traffic in the United States doubles in about 16 years, the total length of the development period for the competitor is taken as 17 years. At the end of this period, the physical property and the density of traffic are assumed to be identical with those of the Virginian Railway, as of the date of valuation.

4.—Through experiment, it is found that a 13% rate increase over that actually in effect during the history of the Virginian Railway is necessary during the period of development of the competitor's business, in order that, at the end of the development period, the competitor shall be earning 6% on its original cost to date. A comparison of the essential data of the Virginian Railway with that assumed for the competitor is shown in Table 3. Table 4 is a comparison of the actual financial history of the Virginian Railway with that history as it would have been if the rates had been 8% higher, and also with the financial history of the competitor with a 13% rate increase.

An examination of Table 4 indicates that the Virginian Railway was not earning 6% on its cost to date to the date of valuation, but that an 8% rate increase would have accomplished this. The effect of this 8% rate increase is to reduce the original cost to date from the actual $69 522 883 to $65 996 540. This last amount compares with the original cost to date of $70 882 787 for the competitor (with its 13% rate increase). This difference of about $5 000 000 represents the value accruing to the property because of the abnormally good judgment used in selecting the Virginian Railway for investment. This enterprise was located so that its rate of growth of business caused it to double in 6 years, whereas the normal rate of growth of railroad business in the United States requires about 16 years.

None of the figures used in the preceding study of the railroad included any amount for depreciation, although it is probable that about $5 000 000 of accrued deterioration (loss of useful life of the simple parts of the property) existed as of the date of valuation. If it is to be

Net earnings last year	3 331 957	3 923 187	4 292 707

assumed that this amount should have been covered by adding a depreciation charge to the maintenance expense and an actual cash reserve established, then it is evident that the original cost to date would have been increased by this $5 000 000. Inasmuch as no such cash reserve has been established, the amount of this reserve would have to be deducted from the original cost to date, in arriving at the value of the property as of the date of valuation. The net result is exactly the same as if depreciation had been entirely ignored—as has been done in the preceding computations. There is nothing in the history of the Virginian Railway to indicate that its physical condition as of the date of valuation was such that maintenance expense in the immediate future would be either abnormally high or abnormally low. Consequently, in so far as depreciation is concerned, there is no need for considering prospective profitableness in connection with the determination of fair value.

SUMMARY.

The Prospective Competitor Method of valuation of property subject to competition is dependent for its successful use on the proper selection of two items, for neither of which the method provides a determination which, in its last analysis, does not depend on the judgment of the user. These two items are: (1) the earning power which the competitor is assumed to have at the commencement of normal operation (say, the second year of operation in the case of a railroad); and (2) the rate of increase of earning power.

Inasmuch as the public does not underwrite the cost of abnormal errors of judgment, among which may be classed the inception of an enterprise where there is not yet a normal public demand for the product, and inasmuch as, consequently, the owner of the property is entitled to reward where exceptionally good judgment has been used, it is evident that these two items must be selected so that they represent normal or average conditions rather than those actually confronting the property under valuation.

With reference to the rate of increase of earning power, the problem is comparatively simple, inasmuch as the average rate of growth of earning power of a given industry in a competitive district is readily ascertainable.

There are several points of view from which the consideration of the earning power to be assumed for the first normal year of operation can

be considered. First, we may consider past history. What was the earning power of the first year of actual enterprises of the character under consideration? The objection to using these data is that the earning power awaiting one enterprise might be satisfactory and yet might be entirely unsatisfactory for a different enterprise requiring a greater initial outlay.

A second point of view is that which considers the normal character of capitalization of enterprises. The early expenditures for construction, etc., must be borne by the owners. After construction has proceeded so far that there is a property having a considerable tangible value, then it is possible for the owner to seek financial assistance through mortgaging his property; especially is this true if a definite earning power has been developed. If, therefore, the initial earning power of the competitor is sufficient to pay operating expenses plus interest on one-half the cost to that date, a definite basis will be established for securing additional capital through a bond issue equal to one-half the cost to such date.

To illustrate: The original cost to the end of the second year of operation of the Virginian Railway's "competitor" was about $56 000 000. Interest at 6% on one-half this sum is $1 680 000. Operating expenses for the second year are estimated to be $2 800 000, the sum of the two items being $4 480 000 as against the $3 671 224 gross earnings actually earned by the Virginian Railway during its second year of operation (at rates apparently much too low).

The history of five other properties shows a second-year gross of from $3 300 to $9 600 per mile of road, that of the Virginian Railway being about $4 600 per mile.

DISCUSSION

Mr. Snow. J. P. SNOW,* M. AM. SOC. C. E. (by letter).—This very interesting paper shows clearly that when public regulation is applied to competitive industries a different method of arriving at a proper base for return from rates is needed from that which is proper to use in determining the corresponding base for industries essentially monopolistic in their nature. It also shows the impossibility of drawing a line of demarcation between typical public utilities and ordinary industries which depend on the public for customers. The fact touched on by the author that simple industries tend to be regulated automatically by natural competition, cannot be depended on to control sufficiently many classes of business in this organizing age.

Mr. Byers favors a rate base dependent on earning capacity. The writer fully agrees to this proposition as applied to the relative bases in groups of competitive industries, but prefers the straight reproduction cost as the base for essential monopolies. The substitute plant method, with estimated income and assumed rates, recommended by the author, leads to such wide fields of conjecture that it can hardly be approved.

In the case of a distinct monopoly, even when competition is feasible, like Mr. Byers' instance of the small water supply system described on page 1333, the matter should be decided by the question "what is fair" to all interests concerned, which in this case is 10 cents per 1 000 gal. The proprietor of the former water wagon, whose business is disrupted by the new system, although an interested party, gets no compensation under the present laws.

The well established rule of regulation upheld by the Courts so far as their knowledge goes, is to fix rates based on proper cost of service allowing a fair return on the fair value of the property required in that service. There are many difficult details in fixing upon fair value, and one that has led to much discussion is the so-called "going value" of an enterprise. A better name for this element is "development expense", as intimated by the author, and it is to be hoped that the former term will drop out of the literature on this subject as seems to be the present tendency.

In case of competitive industries, as Mr. Byers states, the cost basis cannot apply in fixing individual rates. The railroads of the United States furnish a splendid and tremendous example for discussion of this statement. As a whole the railroads are competitive, although there are many feeder lines which are, in themselves, strictly monopolistic. In general, these feeders are short lines, but this is not true to a sufficient extent to justify treatment as a "short line" class as seems to be the present vogue. The distinction of having only one

* Boston, Mass.

terminal or junction with other lines of rail or water transportation is a better means of differentiation from competitive lines than the terms "short" and "through" systems. The terms "competitive" and "non-competitive" may suffice for our purpose. Mr. Snow.

It is thought that the rate base for the non-competitive class should be fixed upon individually as previously indicated for essential monopolies. For the competitive class, which includes the great bulk of the mileage of the country, the only proper basis for relative rates, in the writer's opinion, is the normal income of the individual roads as compared with each other. The total return on these roads in the aggregate should be a fair rate on their aggregate valuation as determined by the Interstate Commerce Commission, using the system which it has laid down as fair. This aggregate return should be pro-rated among the various roads according to their normal earning capacity as measured by the rental recently agreed on by the Railroad Administration and the various corporations. These apportionments, capitalized at an agreed-upon rate, will be the rate bases or authorized capital of the said corporations.

The new adjustment of capitalization thus provided for is drastic, but it settles the vexed question of strong and weak roads; it satisfies the aspirations of those who hold that fair value is based on earning capacity so far as competitive roads are concerned; and, in the aggregate, it satisfies those who hold that return should be based on proper cost of plant.

The fact that the final valuation of all the roads is not yet completed and agreed on need not delay the determination of individual apportionments of capital, because the work is far enough advanced so that an aggregate fair value for all roads could be computed with sufficient precision. In fact, the probable error in fixing the proper rate of return to apply to this aggregate valuation will far exceed in its effect any lack of precision in the latter. The valuation fixed on for a given road would not affect the rate base of that road at all.

This method, in the writer's opinion, presents the fairest and most defensible way of placing the railroads on a proper capitalization base, that it is possible to devise.

C. E. GRUNSKY,* M. AM. SOC. C. E. (by letter).—The writer can see no objection to a comparison with a prospective competitive enterprise, as outlined by the author, when public utility rates are to be fixed, but fails to see therein a generally acceptable solution of the problems which the fixing of rates presents. It is fundamental that the legitimately invested capital—computed at present-day prices—should be protected and ultimately returned to the owner (unless the public utility has perpetual life), and that the owner of the utility is Mr. Grunsky

* San Francisco, Cal.

Mr. Grunsky.

entitled to compensation, in addition to interest on the investment, for rendering a valuable service to the public. He has created wealth for the community at large throughout the territory which his public utility serves and is entitled to a share thereof. His reward should appear in earnings somewhat greater than operating expenses and interest on the investment. Generally, the amount of such reward or compensation can be brought into a satisfactory relation to the volume of business, that is, to gross receipts, and after interest on investment and operating expenses have been ascertained, the "going value" can readily be computed from the surplus of gross receipts in excess of these items.* This is in line with the author's statement "that, contrary to the general view, it is practically much more convenient first to ascertain fair rates and then therefrom to ascertain fair value, than to proceed in the opposite direction." He would be quite right in this statement if he had restricted the same to that portion of the rates or earnings which is to create that indefinite something generally referred to as "going value" (to be distinguished from "going concern value", which usually is held to mean the exchange or market value of the business in its entirety).

The author falls into the usual error of the Courts when he says: "In case of rate regulation, the owner is entitled to such rates as will enable him to earn a fair return on the fair value of his property." He overlooks what seems axiomatic, that value results from the fair rates and that what the Courts should insist on is the protection of the legitimate investment plus adequate compensation for having brought the service of the public utility within the reach of a community. The writer in extending these comments on valuation for rate-fixing purposes will make use of his discussion of a recent paper on "Rational Valuation", by Mr. James Rowland Bibbins, prepared for the Spring Meeting of the American Society of Mechanical Engineers, at St. Louis, Mo. (May, 1920).

Mr. Bibbins is right when he says, in the paper referred to, that, in the matter of valuation procedure, the Engineering Profession should establish the guide posts of progressive thought, courageously, fairly, and without undue dependence upon legal precedents, giving due weight to decisions of the Courts and commissions, but only in so far as these are sound in the light of true engineering economics." The difficulty which has frequently resulted from too strict adherence by valuation engineers to the opinion of the Court in the famous Smyth *vs.* Ames case, that value must be made the basis of the calculation, the starting point, when public utility rates are in question, is well known. How earnest has been their effort to reconcile value and the rate base, and how frequently have they been driven to cover in attempting to

* "Public Utility Rate Fixing", by C. E. Grunsky, p. 55.

Mr. Grunsky.

demonstrate value when they should have been looking for something else that would be a better basis for a rate calculation. They have allowed themselves to put into the word "value" new meanings, making it stand for something which is not value at all. Then, there is that other illustration, the decision of the United States Supreme Court in the Knoxville case, which apparently closes the door against past history with the words:

"If, however, a company fails to perform this plain duty and to exact sufficient returns to keep the investment unimpaired, whether this is the result of unwarranted dividends upon over-issues of securities, or of omission to exact proper prices for the output, the fault is its own."

Referring to the need of being conversant with the historical facts in controversies between corporations and the public, Mr. Bibbins, in the same paper, says:

"It is no exaggeration to say that much of the controversy over valuations could have been avoided entirely had it been possible for the contending parties to view the complete facts concerning which there could be little or no argument."

He is right again, and it is to be hoped that the better access to facts which may be expected in the future—after some years of operation under control—will go far toward establishing that mutual confidence which is essential as a basis for satisfactory service, and will open the door to full historical review, despite such views as have been expressed in the Knoxville and other cases.

The simplest possible valuation problem may be selected as best adapted to illustrate fundamental principles. It will not be necessary to give more than passing note to the more involved problems which require analysis of franchise obligations and restrictions or which are concerned with enterprises subject to a bonded debt. Neither need valuation of any property be considered the rates of which are not subject to regulation, because it is only when the earnings of a property are subject to regulation that the valuation expert has to deal with the problems that have been rendered obscure by the requirement that ascertainment of value shall precede and be made the basis of the determination of net earnings.

The Courts are required to prevent the taking of property without adequate compensation. Whenever public utility rates are established so low that present and prospective earnings will not yield a fair return on the legitimately invested capital, the owner of the utility properties will find that either he is being deprived of property without his consent or that the enterprise was ill-advised and cannot have a value fully equal to the legitimate investment. The Courts when inquiring into the sufficiency of rates are concerned, therefore, with both the legitimate investment and with value.

Mr. Grunsky.

By legitimate investment is meant the reasonable present-day investment which would be required to reproduce the properties in question. It may refer to these properties either in a new condition, or in their present-day or depreciated condition. For rate-base purposes it may suffice to know only the former. For valuation purposes in the proper sense of the term the latter must be ascertained. In the case of every going concern, the investment will include such items as the cost of establishing the business, it being always assumed that the included items can be classed as legitimate.

For the purpose of illustrating fundamental principles, consideration may now be given to the simple case of a public utility enterprise subject to rate regulation, which has been financed by its owners and is not burdened with debt. If such a property is owned by a corporation, as will usually be the case, the stockholders will have been assessed to provide the capital for the investment in the public utility properties. On this capital the owners will expect and should get a fair interest return. The earnings, present and prospective, must be adequate to meet all operating expenses, including a fair allowance for the replacement of the perishable parts of the plant whether consumed rapidly or slowly, and, in addition, they must provide for an adequate interest return on the investment. The earnings must also provide for the gradual amortization of so much of the original investment as will leave a balance on which interest should be earned in perpetuity. This is on the assumption that the public utility in question will have such a long probable life that it may be regarded as perpetual. If, however, the term can be fixed either accurately or approximately in which the utility or any other business will run itself out, the earnings must include a further allowance for the creation of a surplus which, in the probable life of the business, will return to its owner the entire amount of his investment, except, of course, any residual values which may be recoverable when the business is closed out. All this is fundamental and simple; but in the practical application there may be great variation from this or any other clearly defined method of procedure.

Ordinarily, for example, there will be losses in the early years of operation. Provision may have been made to amortize these within a reasonable time, or they may have been regarded as a part of the cost of establishing the business and be treated exactly like other capital invested in the business. When, after a time, rates are to be regulated this cannot be done without historical inquiry, and if such inquiry is barren of results, arbitrary action, such as circumstances seem to warrant, may have to be taken.

Or, again, when public utilities are under investigation it may well be asked: What should be the rate of return? Should this rate be the same at different times and places and for different utilities?

Mr. Grunsky.

And what treatment shall be accorded to that public utility which can show a large output of service as the result of a trifling investment of capital? What intangible values shall the earnings be allowed to create? These questions at once suggest that full justice will not be done when the owner of a public utility is allowed a bare interest return on the legitimate investment. The public utility has contributed to the prosperity of the community. Its owner is entitled to share in this prosperity. A bare interest return on his investment would be inadequate. Not only this, but he is entitled to compensation for the hazards which he has assumed, for his ability to command funds, for his superior business skill, and for management. In ordinary private business affairs compensation for the service such as he is rendering, apart from salaries, would most likely be based on the volume of business. Why not also in the case of the public utility? If this principle of compensation is accepted, there need be no further effort to evaluate "going value" as a component part of a rate base. The aggregate value of all intangible elements in excess of the cost of acquiring them, would result at once from a capitalization of all net profit, including the proposed commission on the volume of business in excess of interest on the investment. Going value will then appear as a result of the rates and not as a part of the rate base. By such a common sense inversion of present-day procedure, the difficulty will be overcome of fixing the fair rate of return in the case of the express company and other public utility corporations which may do a tremendous business on a trifling investment. The trouble in these cases heretofore has been caused by the endeavor to find something intangible to evaluate, in order that the value of physical properties, or the apparent investment, as the case might be, could be swelled to such magnitude that it might with some propriety serve as the rate base.

No satisfactory basis, however, has yet been found for evaluating all the intangible elements. In some cases, to be sure, it can be shown that it has cost something to establish the business. Such cost is usually a legitimate investment and, therefore, properly incorporated in the rate base; but it is not a measure of going value or of any other intangible element. If it was, a premium would be placed on bad management or on the least advantageous venture, which is a repugnant proposition. Because in all the years in which valuation and rate-fixing problems have been receiving the best thought of engineers and economists, no one has suggested any satisfactory method, standard or norm, for measuring the value of intangible elements other than with the aid of capitalized net earnings, should not the engineer be the first to admit the absurdity of "trying to lift one's self over the fence by pulling on one's boot straps", and, having made this admission, should he not contend for a fair excess of earnings over operating expenses, including interest on the investment,

Mr. Grunsky.

thereby creating such intangible values as will fit the circumstances of each case.

An express business may serve again to illustrate this point. Suppose that the legitimate investment in physical properties on which there should be a return, is $1 000 000, that the cost of doing business, not including interest on the investment, is $3 000 000, and that the outlook for a continuation of the business is such that amortization of capital need not be taken into account. Ordinarily, the value of the business as a rating base would be sought by adding some kind of an estimate of going value to the $1 000 000 of legitimate investment; but without considering net earnings—which the rates are to produce—there is no way of getting at going value. Why not, therefore, proceed as follows: The express company is reasonably entitled to a 10% commission on the volume of the business transacted, besides fair interest on its investment in physical properties. Interest on this investment at 8% would be $80 000. This amount added to the cost of operation and to the commission which, at 10% of the gross receipts, would be $342 000, will make $3 342 000. The aggregate excess of receipts over operating expenses should then be $342 000, made up of $80 000 interest on the investment and $262 000 as the earnings attributable to going value. This amount capitalized at 8% will make the going value, in this case, $3 275 000.

The work of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities,* of the Society went far to simplify the problems which are presented to the valuation expert, but the Committee lacked the courage to place itself in opposition to the decisions of the U. S. Supreme Court. It failed to make the point that value cannot be the rate base when public utility rates are to be fixed, because value results from earnings present and prospective and earnings result from the application of rates. It also failed to recognize that instead of evaluating going value as a constituent element of the rate base, earnings should be allowed, which, in the opinion of those who have themselves had experience or who are conversant with the business experience of others, will, in due time, create a fair going value. Naturally, in reaching a conclusion on this subject, the expert will compare the going concern with a new business of similar character and will endeavor to ascertain what early losses and other sacrifices may reasonably be assumed to be or to have been necessary to make the business a going concern and, by his findings in this respect, he may shape his conclusion as to what going value should be created, in order that the owner may ultimately recover the full measure of his legitimate investment and that he may be fairly compensated. As

* *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 1311.

stated in another connection, however, the early losses and deficiency of earnings in the early years are not necessarily the measure of any intangible value. Mr. Grunsky.

In this matter, the Committee correctly notes that there may be a legitimate cost of establishing a business and is right, too, when it says:

"The Committee aims to clarify the subject by assigning all costs * * * to the appropriate items of the reproduction schedule, and by classing the costs and losses of the development period as development expense and confining going value strictly to its intangible aspect, depending on a study of the income account which reflects the advantages accruing from enlarged business, social growth, and other factors of improvement and progress."

As previously noted, every public utility—necessary utilities being assumed—should be allowed to share in the general prosperity which it helps to promote. No hard and fast rule, however, can be laid down for determining what the utility's share should be. Take, for example, the Water Company which owns broad acres for reservoir and watershed purposes, and apply the principle laid down in the Consolidated Gas Company case in which the Court says:

"And we concur with the Court below in holding that the value of the property is to be determined as of the time when the inquiry is made regarding the rates. If the property which legally enters into consideration of the question of rates has increased in value since it was acquired, the Company is entitled to the benefit of such increase. This is at any rate the general rule. We do not say that there may not possibly be an exception to it where the property may have increased so enormously in value as to render a rate permitting a reasonable return upon such value unjust to the public."

If this view of the Court is accepted, as it is by those who consider rate base and present value synonymous, the question is where to stop. It might, as the Court foresees, be quite as improper, in certain cases, to allow to the owner of a public utility a return on enormously increased values of real estate, as it would be, by fixing inadequate rates, to prevent the owner of a utility which has no appreciating items of property, from enjoying any of the unearned increment which he has helped to create.

It should be noted in this connection that appreciation may result from various causes. The increasing population of the country with the resulting development of resources brings land progressively from a lower to a higher use. With the demand for each higher use the value of the land increases. Certain types of property improve and become more valuable with age. This is true of earth embankments. Or, again, property may become more valuable by reason of the shrinking value of the money unit, which is at present painfully apparent in the long continued rise of prices. How then shall a

Mr. Grunsky.

conclusion be reached as to the legitimate investment? What is the sacrifice of the owner of the utility which is to be protected? Surely not an evaluation thereof on his actual money investment, as, for example, in the first years of this century when the dollar would buy two and one-half times as much as it will buy to-day? Must present-day prices then be considered? And, if so, what are the present-day prices? Shall those prevailing at some instant of time be applied? Preferably not; perhaps it will be best to apply average prices during a period recently passed, in which it may reasonably be assumed that the property in question could have been reproduced. Under the ordinary procedure of rate-fixing, however, will it then be possible to escape from the necessity of frequent re-valuation and re-fixing of rates if this principle is to be applied? Or, putting the problem in a somewhat different way, does not the fixing of rates for a definite or indefinite period of time involve more or less speculation, based on the gain or loss which may result from a fall or rise in the value of the money unit?

Organized labor, for example, is fairly successful in securing higher wages when the cost of living increases, when the value of the dollar goes down. Would it not be possible without frequent re-valuation to find a method under which rates would be changed automatically whenever there is a material change in the value of the dollar? Value is here, of course, used in the sense of desirability in exchange. Money is valuable only because it can be exchanged for things which man has come to regard as necessary or desirable. It is convenient as a medium of exchange; but it is not a desirable standard on which to base future payments, though serving well as a standard of value in transactions which do not involve deferred payments.

By common consent, valuations are made in terms of money; but, as stated, money is not a satisfactory standard of value when the time element involved in a transaction is material. The valuation of five years ago is not applicable to-day, not only because there have been relative changes of value as well of labor and of commodities, but, also, for the more cogent reason that the purchasing power of the dollar when measured by the things which are desirable and of which many have entered into plant acquisition and construction, has materially decreased. It is, fundamentally, just as important to use a dependable standard or norm of value as it is to apply correct principles of valuation and rate-fixing. After the experience of the last five years during which, under the influence of currency inflation and other causes, commodity prices and wages have been vaulting to unprecedented heights, can any one still claim that the money unit—the dollar—is an all-round satisfactory standard of value? The best that can be said for money in this connection is that, although it serves as a

Mr. Grunsky

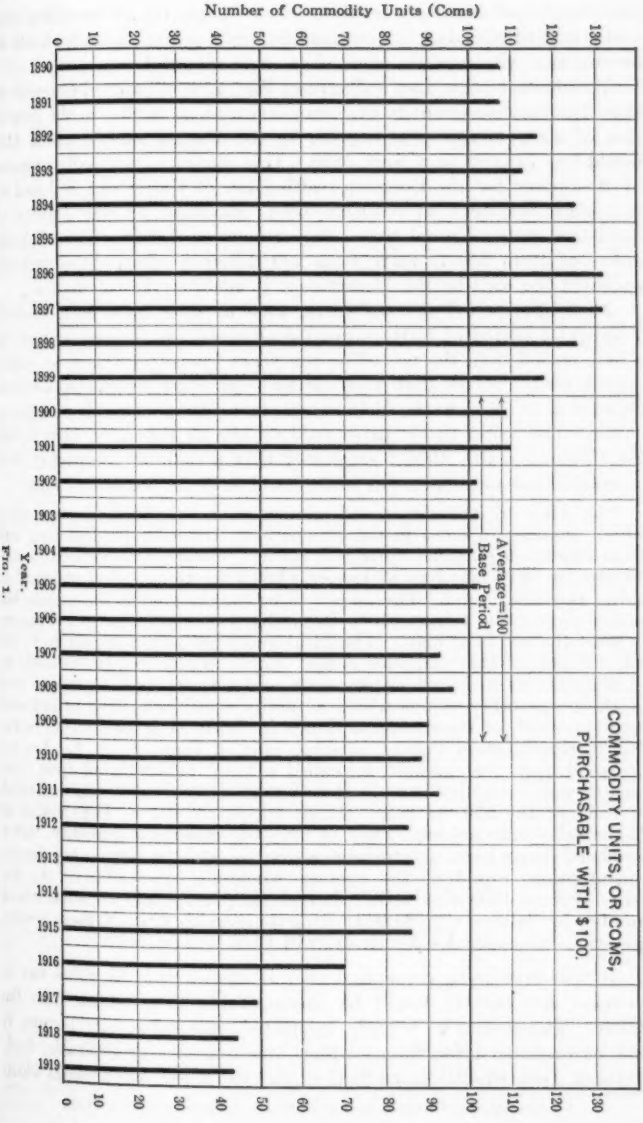

FIG. 1.

Mr. Grunsky.

convenient and necessary medium of exchange, its serviceability as a sole standard of value is questionable, and its use as such should be discouraged whenever the time element is material.

To illustrate this fact a diagram, Fig. 1, is submitted herewith to show the variable quantity of commodities of all kinds, in the proportion of their annual consumption in the United States, which $100 would buy in each year since 1890. This diagram, originally prepared by the writer for the Commonwealth Club of California, is based on the index numbers which have been computed by the Bureau of Statistics of the United States Department of Labor. The wholesale prices of from 250 to more than 290 different commodities properly weighted are used by the Department in making the calculation.

As a base period the ten years, 1900 to 1909, have been selected. This was a period of fairly normal conditions. It is more suitable as a base period than the preceding ten years (sometimes used by economists), for the reason that these earlier years cover a period of business depression in which the dollar had more than normal purchasing power. The writer in the paper read by him in February, 1920, before the Commonwealth Club,* suggested that a definite commodity unit be established to supplement money and said in this connection:

"In view of the defects of money as a standard, having value which changes in consequence of currency inflation or depletion, and from other causes, some other less variable standard of value as a substitute for or to supplement money when functioning as a standard of value, must be found. This is not to be sought among the metals, but rather among the things which in civilized communities are necessary to meet the wants of man. The ideal and what would appear to be the natural unit of this character is that which, in any country, is made up of definite quantities of staples, such as food and fuel, iron, and each of the many other things which a family requires to live in ordinary comfort—each of these several things in fairly close proportion to the family consumption thereof in some unit of time * * *. Let the proposed unit, for example, be called a 'com' (abbreviated from commodity unit), and let it be supposed that to start with the quantities of each of the 250, or more, things which the U. S. Department of Labor takes into account when it fixes the general commodity, 'index numbers' have been determined which, in the proportion of family consumption, would at the average wholesale prices during the ten years 1900 to 1909 (inclusive), have been purchasable for some round number of dollars, say, $1 000. One-thousandth part of these several quantities considered collectively, will then be one 'com'."

It will readily be recognized that if such a unit of value was in common use that it would be incomparably more stable than the dollar. The dollar, as already intimated, has value only because it can be exchanged for things which are necessary or desirable, food, clothing, fuel, education, recreation, and the many other things which

* *Transactions*, Commonwealth Club of California, March, 1920.

Mr. Grunsky.

contribute to human comfort and well-being. The "com", on the other hand, represents a fixed measure of the desirable things themselves. Salaries, wages, and rents, and, in short, all obligations to pay at a future time, should be specified in coms and not in dollars. At the consummation of each transaction in coms, however, the settlement would still be made in money. The money equivalent would be ascertainable by a multiplier, the number of dollars then equivalent in value to a com.

Under such a system of evaluating the relative desirability of things and services, each country could proceed independently. The commodity unit could be adapted to the local standard of living. The commodities which taken collectively will best represent value, in the sense of desire to possess, would in each country be selected with a view to their inclusion in quantities bearing a fair relation to their proportional consumption by the family and the individual.

As already stated, money as a medium of exchange, when the commodity unit comes into general use, will be as necessary as heretofore. Would it not be possible, may be asked, to let the com supplant the dollar? This is practically what Professor Irving Fisher is endeavoring to bring about—the stabilization of the dollar. He would have the quantity of gold in the dollar vary to keep pace with the changing value of money. Legislation would be required to accomplish this and complicated government control, the successful attainment of which does not appear to be within easy reach. Nor is it necessary. Alongside of the com as a norm of value, whether legally recognized or not, money would be used as we use it to-day, and would always be specified in transactions which are unaffected by the time element. It would be used in the ultimate consummation of every business transaction.

Much more might be said on this subject which is not new,* but it would carry this discussion too far afield. However, may it not be suggested, that the change in the value of the money unit as measured by the com might, with propriety, be used in some fashion to secure a correlated automatic increase or decrease of public utility earnings. Frequent revaluation at present-day prices might thus be made un-

* The idea of making a commodity unit the standard of value seems to have been suggested as early as 1822, in his "Present State of England," by Joseph Lowe, who pointed out the need for such a standard in long-time contracts. The same idea occurred to G. P. Scrope a few years later and is discussed by him in "Inquiry into the Nature of a Just Standard of Value", and other publications. Professor Jevons discusses these plans in "Money and the Mechanism of Exchange". Among others who have discussed and approved the use of a multiple standard, may be mentioned, Count Soden, Professor Roscher, Professor Walras, F. A. Walker, Simon Newcomb, Alfred Marshall, E. B. Andrews, Thomas E. Will, Henry Winn, Frank Parsons, A. I. Fonda, J. Allen Smith, C. F. Taylor, Elitweed Pomeroy, and Irving Fisher. Some of these economists not only approve the general principle involved, but have advocated the incorporation of the multiple unit into the monetary system, while others would use it in some way to regulate the volume of the circulating medium.

Mr. Grunsky.

necessary, particularly if the rate base itself was noted in coms instead of in terms of money.

The writer would suggest in keeping with the foregoing comments that to the glossary of valuation and rate-fixing terms there be added:

Rate Base.—That amount expressed in money on which the owner of income-producing property is entitled to a fair interest return. Preferably, the legitimate investment computed at present-day prices, which the writer would call the "natural rate base."

Going Value.—(As Distinct from Going Concern Value).—That portion of value in excess of the legitimate investment which results from a capitalization of so much of the net earnings as is in excess of fair interest on the natural rate base as previously defined. In this sense, going value will include the value of such intangible elements of value as franchises, water rights, special privileges, and the like, except to the extent that, by reason of investment, these are already made a part of the rate base. It is to be treated as a result of earnings and not as a part of the rate base.

Commodity Unit, or Com, for the United States.—(To Be Hereafter Specifically Defined by Law).—The standard or norm of value whenever in any transaction, such as the fixing of a wage or salary or public utility rates, the time element is material. As a preliminary suggestion, for the United States, the compound commodity equivalent of one dollar during the ten years, 1900 to 1909, inclusive, as determined for these years from the index numbers of economists, based on all commodities, weighted according to their relative annual consumption in the whole country, may be accepted as one com, and the prevailing index number will then establish the value of the dollar in coms for any particular date.

Mr. Mayer.

JOSEPH MAYER,* M. AM. SOC. C. E. (by letter).—This paper deals mainly with the difficult problem of the valuation of regulated monopolies.

The valuation and regulation of monopolies are connected so closely that they cannot be investigated independently. Experience has shown that in many important industries, competition—the modern means for securing fair prices—is either impracticable or inadequate to prevent excessive prices and profits. (In this discussion, the word "profit" will stand for "rate of profit"). Regulation of the prices of the products or services furnished by such industries, therefore, was established to fix such prices as will produce the same profits in monopolized and competitive industries.

Two different aims are pursued by the regulating commissions controlling different industries. Some endeavor to secure the same

* Los Angeles, Cal.

Mr. Mayer.

average profits in the regulated industry as prevail in otherwise equally attractive competitive industries, while permitting very different profits in individual enterprises. The Interstate Commerce Commission has practically aimed at this policy, or was compelled to follow it by the partly competitive nature of the controlled enterprises.

Other regulating commissions have aimed at standard profits in successful, controlled enterprises about equal to average competitive profits. They fix a permitted maximum profit which may not be exceeded. If, however, the profits attainable by practicable prices are inevitably smaller, the company and not the public has to bear the loss. Successful enterprises which are easily able to earn the maximum allowed profits have then little inducement for avoiding waste by excessive salaries, high costs of materials used, or for the adoption of improvements, since they would have to bear possible losses without securing any profit therefrom in case of success.

The aim of a perfect regulation must evidently be to give to each individual enterprise its savings achieved by high efficiency as well as the losses resulting from inefficiency or bad judgment, while preventing the excessive prices made possible by monopoly. The policy of fixing a maximum permissible profit without regard to efficiency will inevitably frequently lead to waste and retardation of progress. With such a policy, the allowed maximum profit must be larger than the average competitive profits, otherwise the necessary capital for extensions and improvements cannot be secured. To avoid the harmful effects of a fixed maximum profit, some commissions endeavor to fix prices which give with average efficiency about the average competitive profits and provide for sharing between the public and the companies the excess profits secured by superior efficiency or other causes.

The attempt to prevent inefficiency of management leads inevitably to permitting profits varying with efficiency, and a good regulation endeavors to secure average profits in monopolized industries equal to average competitive profits, while allowing profits varying with efficiency in individual enterprises. The existing regulation and the efficiency of management, together with external causes independent of both, have in the past determined the income from and, consequently, the value of the securities of regulated monopolies, and will do so in the future.

The necessity of regulating monopolies so that the capital required for the needed new enterprises and for enlargements and improvements of old ones can be obtained guarantees (with intelligent regulation and in the long run) that average profits in regulated monopolies will be the same as for otherwise equally attractive investments and competitive enterprises. The actual regulations, however, are only rough and fluctuating approximations to those prescribed by this rule.

Mr. Mayer.

The present and the expected future net return to the investor are the main factors that determine the value of the securities. Other factors of importance are: the current rate of return on similar investments, availability for trust funds, steadiness of prices, and ease of selling indicated by frequency of sales on the exchanges. The investor when he wants to sell is interested in the market price; when he wants to buy, he is interested in the present and future market prices and income. If a security is quoted daily on the exchanges, the determination of its present value is simple, since it is given by the quotation unless there is artificial manipulation. The holder is interested in future income and future values, and, therefore, also in the future regulation which greatly influences them; he values a security because it enables him to sell it when he pleases or to obtain an income from it. Everything that changes either the present or future selling price or the income virtually changes the amount of his property.

Radical changes in the regulation of monopolies change both incomes and selling prices of their securities, they either take away or add to the property of their owners and either give or take equal amounts from others without compensation, unless provision is made for the protection of past investors. They are unjust without such provision unless the previous regulation was illegal. The commissions, the legislatures, and the Courts have endeavored to and must be assumed to have given just decisions in the past, unless the contrary is proven by legal proceedings. The values resulting from past legal regulations and those expected in the near future are the actual and fair values of all past investments. The values which would result from a future regulation radically different from that previously expected are neither actual nor fair values. Since any such regulation, unless accompanied by adequate provision to maintain the values of past investments which would have resulted from the previously expected regulation, is unjust, it would probably not be sustained by the Courts.

The author's valuation would evidently give values radically different from those which have resulted from the past and the expected future regulations. It is, besides, so complicated that, except by mere chance, no two independent investigators would obtain approximately the same results; it is, however, an intelligent and interesting endeavor based on a wide and accurate knowledge of economic principles to find what, in the author's opinion, should be the value of regulated companies, but it does not give the actual or fair value of past investments or of existing regulated enterprises. The chance that such a valuation would be approved by the Courts, the legislatures, or the existing commissions is, in the writer's opinion, extremely remote.

Mr. Mayer.

The actual and generally fair values are given by stock exchange quotations whenever reliable quotations are available. For compulsory expropriation, or sales of large blocks of securities, average quotations for a suitable recent period form the best available measure of value unless recent unexpected events largely modifying future income lead to a calculation from estimated future income, based on the observed relation between income and value for similar investments which by past experience have shown approximately the same relation between income and value. Where no reliable quotations are available, a calculation from estimated future income is the best means of ascertaining the value.

Valuations based on cost of production, or of reproductions of the business, or of a similar business, are practically obliged to neglect the effect on its value of efficiency of management, of unexpected outside factors, and of regulation if any exists, because this can only be measured by the income they produce. The value of a property depends mainly on its future income and is measured by normal exchange quotations if such are available. The actual past, present, and the therefrom estimated future income depends not only on costs, but on efficiency in creating and operating the business, on the regulation of prices, on the efficiency of competitors, and on many other factors unforeseen and independent of the management. The combined influence of all of them is measured by the actual income and the consequent quotations. Therefore, there can be no definite relation between costs and values, as correctly observed by the author, but, unfortunately, the same remark applies to the cost of production of a similar prospective competitor, which would indirectly determine the value of any enterprise by his method of valuation.

The regulation must allow monopolies a fair net income on their fair value. To determine their fair total income, their fair value must be known; therefore, it cannot be determined from their income. This is the apparently conclusive argument for the necessity of a valuation which is not based on income, and this explains the numerous efforts to base valuations on costs. The error in this argument must be shown, in order to justify a valuation of monopolies based on income. The present value of a monopoly depends on its present and the estimated future income, and this depends on the present and the expected future regulation. The present regulation is a known present fact, the expected future regulation is a knowable present state of mind. They determine the present and the estimated future income as far as they depend on regulation, and, with other known present facts, the present value of the monopoly. The actual future regulation is unknown and, therefore, has no influence on the present value of the regulated monopoly. The fair present value of the monopoly can be determined

Mr. Mayer.

from the known present and expected future regulation, and the fair future regulation can be determined from its present fair value.

The proper guiding principles of a fair regulation of monopolies are, therefore, the following:

1.—The average profits of each monopolized industry, of a fairly uniform economic region, and consisting of many individual enterprises, should be the same as those of similar competitive industries.

2.—The profits of individual enterprises of each monopolized industry should be allowed to vary as those of competitive enterprises.

3.—The future regulation should be based on valuations estimating the total present market value, ascertained from incomes and quotations resulting from the present and the expected future regulation, of all the monopolized enterprises of an approximately uniform economic region, and kept up to date by adding the value of all new investments.

4.—The average rate of profit or ratio of net return to market value in similar competitive industries should be ascertained for each economic region. An accurate determination of actual depreciation is required for determining the real rate of profit in competitive or monopolized industries.

5.—The actual rate of profit in both the chosen competitive and all the monopolized industries should be kept up to date, and such modifications of rates should be prescribed from time to time as to produce equality of profits in monopolies and competitive industries.

It is evident from the foregoing that a valuation based on quotations and actual and estimated incomes can be used successfully as the basis of a just regulation of monopolies and that there is no necessity, therefore, of inventing a far more complicated method which cannot give correct results since it neglects various factors which largely influence actual values.

Mr. Willoughby.

J. E. WILLOUGHBY,* M. AM. SOC. C. E. (by letter).—The agitation for a valuation of the railways in the United States grew out of the erroneous assumption commonly made that the book value of the railways was greater than the amount of money actually invested in the property. It was also assumed that the railways could be built now for very much less than the actual original cost, due to the advance in the art and appliances of railway construction and due, also, to the greater amount of capital available. It was evident that the values dependent on commission-made rates were not necessarily

* Wilmington, N. C.

Mr. Willoughby.

the values inherent in the industry, and it was felt that the assumed excess of book values over actual reproduction and development costs were losses to be borne by the industry instead of by the public.

The owners of the railways had definite protection in the Constitution of the United States against the confiscation of their property, and that they should appeal to that protection was natural.

It has never been seriously thought that the cost of reproduction of the physical property of any designated railway company is the fair value of the property of that company. The cost of reproduction of such property is merely one of the elements which go to make up the value of the property; and some of the author's remarks on the cost-of-reproduction method are tinged with error as to the purpose of that method.

The writer understands the author's idea to be: That the fair value of a railway property is the capitalization of the net earnings which the property will produce from a general rate level which is sufficiently high to produce such profit from the construction and operation of a competitor as will attract the capital necessary to create that competitor.

The competitor must necessarily procure some part of the existing traffic, and under the assumptions will not, of itself, produce any additional traffic. If, perchance, the general rate level at the time of the valuation is just sufficient, under normal efficiency in maintenance and operation, to produce an investment interest rate on the book cost of the property under valuation, the net earnings from a "fifty-fifty" division of the traffic, within the "reasonable time which capital would be contented to wait", will require a decided increase in the general rate level, in order to attract the capital necessary for the construction and operation of the competitor. The increase in the general rate level will produce actual profits to the property under valuation, which, when capitalized, will augment the value of that property. The proposed competitor method will give fictitious values to the real property and cannot determine, in practice, the fair value of the property under valuation.

Railways are often built for competitive purposes, but such construction is undertaken when there is expectation of additional traffic to be developed; expectation of additional hauls and revenues from traffic already enjoyed by the building company; expectation of obtaining control of traffic—sometimes called for for strategic purposes; and rarely for the division of existing traffic. The experience of the railways in the United States does not afford the data for valuation by the proposed competitor method. When we depart from experience, we get into a maze of theory which is not an aid in fixing the fair value.

Mr. Willoughby. It is a matter for regret that the fair value of the railways cannot be determined on the principles governing free competition, but the author is entitled to the thanks of the Society for the service rendered in his study relative to the application of those principles.

Mr. Hawley. R. W. HAWLEY,* M. AM. SOC. C. E. (by letter).—This paper came rather as a surprise. Even though it proposes the general use of a method of procedure that is in many respects new, there has been such voluminous discussion of the valuation of public utility properties that it seems futile to add anything at this time. It seems doubtful whether the "prospective competitor method of valuation" will actually simplify procedure or result in greater need of justice to all concerned.

It seems to the writer that the author has placed entirely too much stress on the sanctity of private property value. His first basic proposition (page 1314) strikes his keynote. It points, as a thing proven, to the absolute similarity of private property without specific regulation by the State of use, returns or otherwise, and private property called "public utility," recognized by the community as of such general importance that it should be regulated. It is agreed that in this recognition only lies the basic difference in the legal status of properties devoted to the production of anything used by the public.

The writer differs with the statement of this basic principle in that it implies protection of the value of property which is not part of a public utility. If the private owner of a parcel of land must sell, the value of his property is in no way protected by law or the Constitution, while that of a public utility is recognized and has protection far beyond any other property. On the other hand, it is entirely true that the owner of property under no public regulation can sell when and to whom he pleases and the public has no voice in the use to which the property may thereafter be put. It may go from a state of maximum productiveness to a state of absolute idleness. It is due to the fact that the public is vitally interested in the continual operation of a public utility property that there is regulation by public agents under the law and all the details of such regulation are the natural and logical outcome. The difference in status of unregulated private property and public utility property is so absolute and fundamental that the effort of the Courts and Commissions to establish and follow the theory that the property value must be determined as though there were no regulation, has always resulted in approximation without logical bases and argument.

The only basic principle that can be adhered to fully is the assumption from the beginning of control by the public that the owners are agents of the public contracting to provide a certain commodity or service, and that the property involved comprises a site for the con-

* San Francisco, Cal.

Mr. Hawley.

duct of the agency and the tools used in producing the commodity or service. Fair payment obviously will then be return upon the actual investment as rental of the property, and the costs of conducting the business and the cost of its upkeep through a depreciation fund. Where there is no record, or records are incomplete, the so-called historical reproduction cost method of determining the amount of investment to be used would naturally follow.

In carrying the regulation of utilities into a time of relatively high prices such as prevail at present, there is no injustice in adding to the former investment under low prices the actual higher recent expenditures in capital. There is obvious injustice to consumers in allowing the agent at this time a return not only upon the actual expenditure at high prices but the elevation to these prices of all property installed at former low prices. This is manifestly profiteering under the protection of the representatives of the public. If such a course is justifiable in the case of public utilities, there should be legislation to increase the face value or the interest rate on all long-term bonds issued prior to 1914, and moreover, this change should be made periodically or continuously to be in conformity with general business conditions.

The author's third basic principle holding that every enterprise under regulation should have the privilege of earning the same return as though it were in the field of free and open competition, lets down the bars to a field of speculative contention larger than any that are open to contestants before regulating bodies even under the cost of reproduction. Assuming the public utility to be a railway system in comparatively flat country where it does not physically become a natural monopoly, it may be possible of theoretical determination within fairly narrow limits. However, such conditions are not common. A single railway built into or through any territory, with the choice of routes and location of stations and terminals, will generally have great advantages over any other possible railway tapping that territory. A water system, particularly in the West, has generally made use of the only logical available water supply and to base the returns to be paid by patrons upon the cost of providing the same service by means of a simulated competing system could very readily result in the payment of several times what would be a fair return upon the investment of the existing utility. This would manifestly be unjust, and in all probability would result in such water rates as would seriously limit the growth of the community or would actually force the abandonment of business at that point. No utility management would agree to such exorbitant rates as could very readily result.

This basic principle may very well be in direct opposition to the author's basic principle No. 4, which states that the utility is not entitled to returns due solely to its monopolistic protection from competition, and the writer submits that any dividing line will be found

Mr. Hawley.

to be very indefinite. The writer is presuming that the author means legal instead of physical protection. The author's method would result in exactly the arguments that have been put forward by many experts for determination of intangible values, including those assigned to water rights, strategically located real property, and going-concern value.

The author's basic proposition No. 6 that the "market value" of any property results from use or usefulness and the measure or amount of profit that is or can be realized, and No. 7, that the fair value (presumably of public utility property) is measured by the actual or possible returns under fair rates, throws the whole question back into the same indeterminate position as a spoke in the "wheel of things" that confounded the first reformers who began regulation. It need not have been repeated that the returns realized, or to be realized, cannot be used as a measure in this adjustment of rates to build up the same income.

To work by deduction from returns to value of property requires analysis of all factors entering into the cost of maintenance and operation, depreciation of properties, etc. The author's method appears to make all of these things a necessary determination, but on purely hypothetical bases. He avoids the only reasonably well defined data—the records of actual cost in connection with the property that is in use. In this whole subject, the questions of equity involved have been steadily clouded by the habit of the Courts in placing great stress upon the term "value" and insisting that an amount be found which would always be called by that name regardless of its use. The disagreement of Courts, lawyers and engineers even in cases where a relatively small amount of money is involved, has shown clearly that there can be no exact determination of the thing called "value" where any part is an estimate. What all Courts and Commissions have at all times been called upon to determine is the amount of investment or capital used for a purpose, and to be recognized in any transaction between the owner and the patrons, the public, or in financial dealings. The sum used need never be called "value" nor confused with the changing prices that are or may be paid for the items that would go to make up a similar plant or one that would provide the same service.

All the author's discussion under general principles and recommended procedure, Sections 4, 5, and 6, is boiled down, at the bottom of page 1323, to the conclusion that fair value and fair rates are interdependent one on the other; that, therefore, one must be determined first and that it is better to first decide upon fair rates. The author's conclusion is presumably influenced by his discussion of a railroad rather than any other public utility, and railroad rates have generally been determined without any reference to cost or value of plant. This has not been true of other public utilities where a compact unit is com-

Mr. Hawley.

plete and detached from any other similar unit and where there is no basis for determination of rates without reference to cost, actual or assumed, of the particular plant.

In spite of all theorizing, it is not possible to establish similarity between the regulated public utility property and a business operating under free competition. A public utility is fixed in one place, cannot move its plant and cannot actually go into any other business. There is no general field in its own line to furnish a fundamental level of rates or returns. Particularly in the matter of public water supply, there is certain to be great variation in cost found in comparing communities and no reason why one community very advantageously situated should pay the same water rate as another where physical factors make the cost of water service particularly high; nor should it be possible, if the general water rate is determined by measure of the communities easily served, that the utility in the community where the cost is high should lose money.

It must be agreed that the owner of every regulated enterprise is entitled to earn the same profit as, with the same effort and taking equal risks, he would earn if the money were invested under competitive conditions. The author makes this customary statement, however, with the implication that the tendency is to deny the public utility owner his right and he voices grave warning against this course. As a matter of fact, the owner is usually a stockholder who has made his investment without any particular understanding of the business, and those promoting and operating the utility property are, practically speaking, only employees. The only intelligence exercised by the owner or the stockholder was in determining whether to invest. The energy is that of those promoting and operating, and it is difficult for any one to measure the effort put into the building and operation of any particular property. Return to the owner should be a fair rate of interest on investment, and so far as any argument at this point is applicable, it is the actual investment reasonably made and as extensive as the business warrants. Risk is largely eliminated and the scope of the business can be forecast and provided for more closely than is possible in any competitive undertaking. This makes it entirely reasonable that less than the ruling rate of interest for loan to business with a large element of risk be allowed.

Determination of a plant that could be built to give as widespread and adequate service under the conditions obtaining at the time set may be a fair measure of price to be paid in a transfer. To be fair, this should eliminate from consideration the actual existing plant completely. Once the existing property is recognized, it is necessary to recognize its history. Otherwise, the reasons for construction in the present location and with the existing type of construction would often be an absurdity.

Mr. Byers.

M. L. BYERS,* M. AM. SOC. C. E. (by letter).—The writer has read with interest the discussions on his paper. As was to be expected in such an intricate matter, evident misunderstandings have occurred, which a more careful reading of the paper probably will correct.

In the special case cited by Mr. Willoughby, namely, a property on which no increased traffic is expected, the process, in a general way, would be somewhat as follows:

1. Assume the competitor's first year's business, in ton-miles, passenger miles, etc., as one-half that of the property under valuation.

2. Assume this to grow at the normal rate for normal properties of this character, this growth to continue until it equals that of the property under valuation as of such date.

3. In the absence of known unwise construction, take the construction plus additions and betterments as equal to the cost of reproduction, at present-day prices, of the physical property under valuation.

4. Find the rate level which, in the time allowed, would just give a fair rate of return on the cost to date of the competitor.

5. Capitalize the net earnings of the property under valuation on the basis of this rate level. The result is its fair value.

This process would involve little more than finding "cost of reproduction"; also, it would not necessarily require a decided increase in the general rate level as surmised by Mr. Willoughby. On the contrary, if the property under valuation had been built when costs were higher, it might call for a lowering of the rate level.

Realizing that opinions of what is fair will always differ more or less, the writer has abandoned opinions of "fairness" as the foundation for his paper and instead has founded the argument on the proposition stated at the top of page 1325 that, "the owner of every regulated enterprise is entitled to earn the same profit as the same amount of capital, intelligence, and industry would normally enable him to earn in the field of free and open competition." He offered in defense thereof the foot note on the same page.

To the writer, the crux of this valuation question is outlined in the brief summary of his paper. How is one to distinguish between a property abnormally well conceived, built, and operated and one abnormally poorly so, in order that he may reward the one and penalize the other? In the questions, *A* to *H*, inclusive, pages 1352-1354, he had hoped to elicit some discussion of these features.

The Prospective Competitor Method seems readily to furnish the answers to these questions.

Paper No 1454

A SIMPLE METHOD OF COMPUTING DEFLECTIONS OF A CABLE SPAN CARRYING MULTIPLE LOADS EVENLY SPACED

By F. C. Carstarphen, M. Am. Soc. C. E.

With Discussion by Messrs. William Hewitt, Edward B. Durham, and F. C. Carstarphen.

Synopsis.

This paper presents a simple method for computing the deflections of multi-loaded spans when the loads are spaced uniformly that can be applied to those calculations which are involved in determining the length of suspender rods for suspension bridges, the position of the rolling loads on aerial tramway cable spans, and the construction of messenger or electric transmission lines.

First, a general description of the method of computation and its dependence on the theory of first and second differences is presented; then the derivation of the several formulas involved, the proof of the general case of a span the terminals of which are at different elevations and carrying n loads, and the solution of practical examples are given.

It is believed that the method is so simple as to appeal to all engineers who have occasion to make calculations of this nature.

The late Dr. Alexander Macfarlane delivered at Lehigh University a series of lectures on the prominent British mathematicians and physicists of the Nineteenth Century. Among others, he referred to Charles Babbage in the following anecdote:

Babbage was sitting one evening in the rooms of the Analytical Society at Cambridge, in a dreamy mood, with his head leaning forward on the table and a table of logarithms lying open before him. Another member entering the room and seeing him thus occupied, said: "Well, Babbage, what are you dreaming about?"; to which he replied: "I am thinking that all these mathematical tables might be calculated by machinery." This chance remark evidently caught his fancy, for it shaped in a large measure the direction of his subsequent career. He became intensely interested in methods for reducing the details of computation, and for this purpose gave his attention to the theory of finite differences.

Babbage is probably best known to the world at large by his ingenuity in preparing the drawings for and partly building machines called the Difference and Analytical Engines. The British Government is said to have subsidized the construction of the Difference Engine at a cost of more than £17 000. It is generally conceded that the principles established by Babbage in these devices pointed the way to the development of the modern computing machines.

The fundamental idea underlying the method of differences may be illustrated by the following properties of the squares of the natural numbers:

Numbers	1	2	3	4	5	6	7	8	9
Square	1	4	9	16	25	36	49	64	81
1st Differences.....	1	3	5	7	9	11	13	15	17
2d Differences.....	2	2	2	2	2	2	2	2	2

For instance, if we write the squares under the numbers, we can find their first difference by subtraction. The second differences are found also by subtraction of the first differences and, in this case, all are constant.

For the sake of illustration let it be assumed that the computation of a table of squares of the natural numbers is a complicated process and that we are endeavoring to discover a method of simplifying it.

Upon an examination of the table of squares and their first and second differences, it will be noted that it is only necessary to add to a square the preceding first and second differences to secure the next square: thus, $9 + 5 + 2 = 16$, or $36 + 11 + 2 = 49$, noting that this is a summation in a diagonal direction. Surely no one would criticize

a computation of this sort because of its complexity. This method may often be used to advantage in computing logarithms and other transcendental functions where the nth difference is not equal to zero, for where a certain number of decimal places only are required, it is possible to secure a difference which is sufficiently near zero to make practicable the use of the method of differences.

It seems that most engineers believe that the properties of curves can only be ascertained by difficult methods of computation. The calculation of the deflections of multiple-loaded cable spans is no exception. The usual formulas given in engineering handbooks for this purpose are either very complicated or are based on the assumption that the concentrated load can be considered as uniformly distributed, and so the practice has become more or less general of adopting graphical methods for solving the problem. The construction of an equilibrium polygon for a large number of loads requires time and skill. The method which follows is so simple and direct that it should be known to all engineers who have occasion to deal with problems of this nature.

The curve assumed by a cable supporting multiple loads is not to be considered as a continuous function, but, on the contrary, consists of $n + 1$ parabolas which intersect beneath the successive loads with an angle the tangent of which is equal to $\frac{g}{t}$, or the weight of the load, g, divided by the horizontal component of the tension in the cable, t. Because of this lack of continuity, all equations for direct computation of deflections are complex.

Strange as it may seem, when the nature of the curves is considered the second differences are found to be constant, similar to the case for the table of squares, and their value is equal to $-\frac{a}{t}(g + w\,a)$, in which

a = Horizontal distance between loads;
t = Horizontal component of cable tension;
g = Weight of load;
w = Horizontal projected weight per foot of cable.

When an odd number of loads are symmetrically placed on the cable with regard to the center of the span, the first differences, exclusive of the slope increment, are equal to one-half of the second differ-

ences; that is, the first differences are $-\frac{a}{2t}[g + w a] \pm q h$, where $q = \frac{a}{s}$, or the load spacing divided by the span.

As this latter case is the one which most frequently arises in practice, the computation of the deflections of such a span by the method of finite differences becomes nearly as simple as the calculation of the table of squares previously given.

Derivation of the Formulas Used.

The derivation of the formula for the deflection of any point along a suspended cable carrying n equal loads evenly spaced, is as follows: To find the deflection at any point P, Fig. 1:

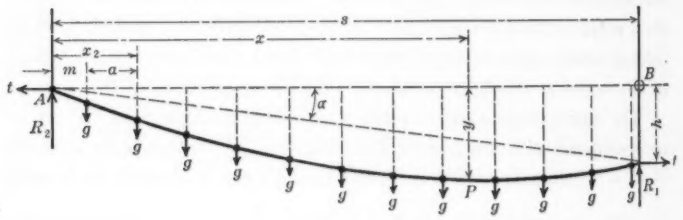

Fig. 1.

Let n = Number of loads on the span;
a = Distance (horizontal) apart or spacing of loads;
m = Distance (horizontal) from R_2 to first load;
h = Difference in elevation of supports;
α = Slope angle;
s = Span (measured horizontally);
t = Horizontal component of the tension;
p = Number of loads to left of x y, or P;
x = Horizontal distance from left support to P;
y = Deflection referred to left support;
R_1 = Reaction at right support;
R_2 = Reaction at left support;
w = Weight per unit of cable multiplied by sec. α;
g = Weight of concentrated load.

For equilibrium:

$$\Sigma x = 0 \quad \Sigma y = 0 \quad \Sigma \text{ moments} = 0$$

that is:

$$\Sigma x = t - t = 0$$

$$\Sigma y = (R_1 + R_2) - (n\,g + w\,s) = 0$$

and by moments about B:

$$R_2 s = (s - m)\,g + (s - m - a)\,g + (s - m - 2a)\,g + (s - m - 3a)\,g$$

$$\ldots + [s - m - (n-1)\,a]\,g + \frac{w\,s^2}{2} + h\,t;$$

that is:

$$R_2 = n\,g - \frac{n\,m\,g}{s} - \frac{n\,(n-1)\,a\,g}{2\,s} + \frac{w\,s}{2} + \frac{h\,t}{s}.$$

Consider any free section, such as to the left of P, that is, P is between the pth and $(p+1)$th loads.

Then,

$$y\,t = x\,R_2 - \frac{w\,x^2}{2} - (x - m)\,g - (x - m - a)\,g \ldots [x - m - (p-1)\,a]\,g$$

and

$$y = \frac{x\,R_2}{t} - \frac{w\,x^2}{2\,t} - \frac{p\,x\,g}{t} + \frac{p\,m\,g}{t} + \frac{p\,(p-1)\,a\,g}{2\,t}$$

$$y = \frac{x}{t}\left(n\,g - \frac{n\,m\,g}{s}\right) - \frac{n\,(n-1)}{2} \cdot \frac{a\,x\,g}{t\,s} + \frac{w\,s\,x}{2\,t} \pm x \tan.\,\alpha - \frac{w\,x^2}{2\,t}$$

$$- \frac{g}{t}\,p\,x + \frac{g}{t}\,p\,m + \frac{p\,(p-1)}{2}\,\frac{g\,a}{t}$$

Hence is derived the general equation, as follows:

$$y = \frac{g}{t}\left[x\,(n-p) - m\left(\frac{x\,n}{s} - p\right) - a\left(\frac{b\,x}{s} - c\right)\right]$$

$$+ \frac{w\,x}{2\,t}(s - x) \pm x \tan.\,\alpha,$$

where $b = \dfrac{n\,(n-1)}{2}$, $c = \dfrac{p\,(p-1)}{2}$, and the $\pm$ sign is used to indicate the direction of the slope.

Since the quantities entering into the foregoing equation are usually of large magnitude, it is often preferable to use the following modified form:

$$\text{Let } \frac{x}{s} = r;$$

$$\frac{m}{s} = v;$$

$$\frac{a}{s} = q,$$

then

$$y = \frac{g\,s}{t}\left[(n-p)\,r - v\,(n\,r-p) - q\,(b\,r-c)\right] + \frac{w\,s^2}{2\,t}\,r\,(1-r) \pm r\,h.$$

With a single load only at the center of the span, the deflection at the load is

$$y = \frac{g\,s}{4\,t} + \frac{w\,s^2}{8\,t} \pm \frac{h}{2}$$

Also, the deflection formula may be altered to give a multiplier for $\frac{g\,s}{4\,t}$ for any number of loads, namely,

Case I.—Odd number of loads, with the middle load placed at the center of the span:

$$y = \frac{g\,s}{4\,t}\left[n - \frac{n^2-1}{2}\,q\right] + \frac{w\,s^2}{8\,t} \pm \frac{h}{2}$$

Case II.—Even number of loads, one of the middle loads placed $\frac{a}{4}$ beyond the center of the span. The deflection at this load is:

$$y = \frac{g\,s}{4\,t}\left[n - \frac{n^2}{2}\,q + \frac{n}{4}\,q^2\right] + \frac{w\,s^2}{2\,t}\left[\frac{1}{4} - \frac{1}{16}\,q^2\right] + \left[\frac{1}{2} \pm \frac{1}{4}\,q\right] h$$

Case III.—An even number of loads placed symmetrically to the center of the span. The deflection of the cable at the center of the span is:

$$y = \frac{g\,s}{4\,t}\left[n - \frac{n^2}{2}\,q\right] + \frac{w\,s^2}{8\,t} \pm \frac{h}{2}$$

The following tabulation for an odd number of equal loads, Case I, gives the center deflection in terms of q:

No. of loads.	Deflection due to load.	Deflection due to cable.	Quantity due to chord slope.
1.....	$\frac{g\,s}{4\,t}$	$\frac{w\,s^2}{8\,t}$	$\pm\frac{h}{2}$
3.....	" (3-4q)	"	"
5.....	" (5-12q)	"	"
7.....	" (7-24q)	"	"
9.....	" (9-40q)	"	"
11.....	" (11-60q)	"	"
13.....	" (13-84q)	"	"
15.....	" (15-112q)	"	"
17.....	" (17-144q)	"	"

No. of loads.	Deflection due to load.		Deflection due to cable.		Quantity due to chord slope.	
19.....	$\frac{g\,s}{4\,t}$	$(19\text{-}180q)$	.... $\frac{w\,s^2}{8\,t}$		..... $\pm\frac{h}{2}$	
21.....	"	$(21\text{-}220q)$	.... "		.....	"
23.....	"	$(23\text{-}264q)$	.... "		.....	"
25.....	"	$(25\text{-}312q)$	.... "		.....	"
27.....	"	$(27\text{-}364q)$	.... "		.....	"

To illustrate the method of determining the center deflection by these formulas, take, for example, the following span:

$s = 2\,000$ ft.

$h = -200$ ft., that is, right support is above left one.

$g = 2\,000$ lb.

$w = 3.6$ lb-ft.

$a = 204$ ft.

$q = \frac{a}{s} = 0.102$

$t = 40\,000$ lb.

It will be noted that when $a = 204$ ft., it is possible to have the following arrangement of loads:

Case I.—$n = 9$, with fifth load at center of span.

Case II.—$n = 10$, with sixth load 1 051 ft. from left support.

Case III.—$n = 10$, with sixth load 1 102 ft. from left support.

Therefore:

Case I.—

$$y = \frac{2\,000 \times 2\,000}{4 \times 40\,000}[9 - 40 \times 0.102] + \frac{3.6 \times 2\,000^2}{8 \times 40\,000} - \frac{200}{2}$$

$= 25 \times 4.92 + 45 - 100$

$= 68$ below left support.

Case II.—

$$y = \frac{2\,000 \times 2\,000}{4 \times 40\,000}[10 - 50 \times 0.102 + 2.5 \times 0.102^2] + \frac{3.6 \times 2\,000^2}{8 \times 40\,000}\left[1 - \frac{0.102^2}{4}\right] - 200\left[\frac{1}{2} + \frac{0.102}{4}\right]$$

$= 25 \times 4.926 + 44.9 - 200 \times 0.5255$

$= 123.15 + 44.88 - 105.10$

$= 62.93$ below left support.

Case III.—

$$y = \frac{2\,000 \times 2\,000}{4 \times 40\,000}[10 - 50 \times 0.102] + \frac{3.6 \times 2\,000^2}{8 \times 40\,000} - \frac{200}{2}$$

$$= 25 \times 4.90 + 45 - 100$$

$$= 67.5 \text{ below left support.}$$

PROOF THAT SECOND DIFFERENCES ARE CONSTANT.

To prove that the second differences of consecutive deflections of equal loads and empty cable of a suspended span are constant, let the following formula give the deflection referred to the left-hand support for any point, xy, Fig. 2:

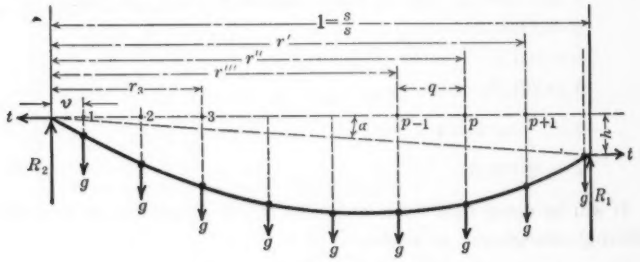

FIG. 2.

$$y = \frac{g\,s}{t}[(n-p)\,r - v\,(n\,r - p) - q\,(b\,r - c)] + \frac{w\,s^2}{2\,t}\,r\,(1-r) \pm r\,h,$$

where the notation is as before and

r = ratio of distance, x (measured from left support), to span, s, that is, $r = \frac{x}{s}$;

v = ratio of distance, m, to s, that is, $v = \frac{m}{s}$;

q = ratio of load-spacing, a, to s, or $q = \frac{a}{s}$;

$b = \frac{n(n-1)}{2}$;

$c = \frac{p\,(p-1)}{2}$.

Before the value of the second differences of consecutive deflections can be found, it is necessary to obtain their first differences; thus, the first differences between deflections at any consecutive loads, such

as p, $p-1$, and $p+1$, can be determined as follows, if for convenience r', r'', and r''' be the distance ratios to the loads, $p+1$, p, and $p-1$.

If y', y'', and y''' represent the deflections, we may write, noting that $r''=(r'-q)$, $r'''=(r'-2q)$, and $(r'-v)=(p-1)\,q$:

$$y'=\frac{g\,s}{t}\left[(n-p)\;r'-v\,(n\,r'-p)-q\left\{\frac{(n-1)}{2}\,n\,r'-\frac{p\,(p-1)}{2}\right\}\right]$$
$$+\frac{w\,s^2}{2\,t}\,r'\,(1-r')\pm r'\,h.\ldots\ldots\ldots\ldots\ldots\ldots(1)$$

$$y''=\frac{g\,s}{t}\,[n\,(r'-q)-p\,(r'-q)-v\,n\,(r'-q)+v\,p-q\,b\,(r'-q)+q\,c]$$
$$+\frac{w\,s^2}{2\,t}\,(r'-q)-(r'-q)^2\pm(r'-p)\,h.\ldots\ldots\ldots\ldots(2)$$

Subtract Equation (2) from Equation (1):

$$(y'-y'')=\frac{g\,s\,q}{t}\,[n-p-v\,n-q\,b]+\frac{w\,s^2\,q}{2\,t}\,(q-2\,r'+1)\pm q\,h\ldots(3)$$

The last term is $\pm$, because the slope may be positive or negative.

Equation (3) is very important, as it permits ready computation of the change in deflection between adjoining loads.

To find the second differences:

$$y'''=\frac{g\,s}{t}\left\{n\,(r'-2\,q)-(p-1)\,(r'-2\,q)-v\,n\,(r'-2\,q)\right.$$
$$\left.+v\,(p-1)-q\,b\,(r'-2\,q)+q\left(\frac{(p-1)(p-2)}{2}\right)\right\}$$
$$+\frac{w\,s^2}{2\,t}\,[(r'-2\,q)-(r'-2\,q)^2]\pm(r'-2\,q)\,h.\ldots\ldots\ldots(4)$$

Subtract Equation (4) from Equation (2):

$$(y''-y''')=\frac{g\,s\,q}{t}\,[n-p+1-v\,n-q\,b]$$
$$+\frac{w\,s^2\,q}{2\,t}\,[1-2\,r'+3\,q]\pm q\,h.\ldots\ldots\ldots\ldots\ldots(5)$$

Subtract Equation (5) from Equation (3):

$$(y'-2\,y''+y''')=-\frac{g\,s\,q}{t}-\frac{w\,s^2\,q^2}{t}=-\left[\frac{g\,a}{t}+\frac{w\,a^2}{t}\right]$$
$$=-\frac{a}{t}\,[g+w\,a]\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6)$$

which is the second difference and is a constant.

When an odd number of loads are on the span and the first differences are desired between the deflection of the middle load when

placed at the center of the span and those contiguous to it, use may be made of the fact that under these conditions Equation (3) reduces to

$$y' - y'' = -\frac{a}{2t}[g + w\,a] \pm q\,h \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

It will be noted that the first part of the second member is one-half the value of Equation (6) for the second difference. Therefore, the calculation of the second difference permits deriving the first differences for Case I in a simple manner. Likewise, for Case III, the first differences are equal to the second differences, slope factors ignored.

EXAMPLES.

The deflection at the loads and the tower heights will be investigated for an assumed span of an aerial tramway across the St. Lawrence River, ends at the same elevation ($h = 0$).

Let s = Horizontal distance between supports = 4 800 ft.
g = Weight of each load = 1 150 lb.
a = Horizontal distance between loads = 375 ft.
t = Horizontal component of tension = 90 000 lb.
k = River clearance = 160 ft.

A.—To find the approximate weight per foot of cable:

Because of the great length of span and the need for keeping the tower heights as moderate as possible, it will be necessary to use a cable of steel capable of working safely under a tension of 67 000 lb. per sq. in. of sectional area. Since the total tension is 90 000 lb., the cross-sectional area of the cable will be $\frac{9}{6.7} = 1.35$ sq. in. Reference to a table of properties of locked-wire cable shows the nearest size to be 1⅜ in. in diameter, having a listed weight of 4.75 lb. per ft.

B.—It is now necessary to know the number of loads (n) on the span:

The number of loads is one more than the integral portion of the quotient obtained by dividing the span by the carrier spacing; that is,

$$n = \frac{4\,800}{375} + 1 = 13 \text{ loads.}$$

The distance, m, from the left-hand support to the first load, when all are symmetrically placed with regard to the center, is found by

dividing by 2 the difference between the length of the span and the sum of the carrier spacing:

$$m = \frac{4\,800 - (12 \times 375)}{2} = 150 \text{ ft.}$$

C.—To find the deflection under the middle load at the center of the span:

The center deflection for this case of an odd number of loads ($n = 13$) is (Case I of the foregoing):

$$y = \frac{g\,s}{4\,t}\,[13 - 84\,q] + \frac{w\,s^2}{8\,t}$$

$$= \frac{1\,150 \times 4\,800}{4 \times 90\,000}\,[13 - 84 \times 0.0781] + \frac{4.75 \times 4\,800^2}{8 \times 90\,000}$$

$$= 98.71 + 152 = 250.71 \text{ ft.}$$

Because of the large value of the center deflection, more correct results can be secured by obtaining the projected weight per foot of cable. This is found by computing the approximate length, l, of the cable in the span as follows:

$$l = s + \frac{8}{3}\frac{y^2}{s}$$

$$= 4\,800 + \frac{2.667 \times 152^2}{4\,800}$$

$$= 4\,812.83 \text{ ft.}$$

The corrected weight of cable per horizontal foot of span is then:

$$\frac{4\,812.83}{4\,800} \times 4.75 = 4.76 \text{ lb.}$$

Since some may question the propriety of using the parabolic formula for the deflection of the unloaded cable, it will be of interest to compute its center deflection by the catenary as well. The parabolic formula is as follows:

$$\frac{w\,s^2}{8\,t} = \frac{4.76 \times 4\,800^2}{8 \times 90\,000} = 152.32 \text{ ft.}$$

A formula for the catenary is:

$$y = \frac{t}{w} \cosh. \frac{w\,x}{t}$$

$= 18\,947.37 \times 1.00803 = 19\,099.52 - 18\,947.37 = 152.24$ ft.

x = Distance from the center of the span to the point, xy; that is, for the center deflection, x will have a value of one-half the span, or 2 400 ft.

Comparing this value (152.24 ft.) with that obtained by the parabolic formula shows a difference of 0.08 ft., which is a sufficiently close agreement to establish the validity of the calculations made by that formula.

Correcting the value of the center deflection as found in Paragraph *C*, there is obtained:

$$y = 98.71 + 152.32 = 251.03 \text{ ft.}$$

As the river clearance is to be 160 ft., and as the bottom of the bucket of the carrier will be approximately 10 ft. below the cable, the minimum height of the shore towers will be $170 + 251.03 = 421.03$ ft., that is, we may say not less than 425 ft.

D.—To resume the calculation of the deflections, compute the second difference by Equation (6):

$$-\frac{a}{t}[g + w\,a] = -\frac{375}{90\,000}[1\,150 + 4.76 \times 375]$$
$$= -12.229 \text{ ft.}$$

E.—The first difference at the center is equal to the second difference divided by 2:

$$-\frac{12.229}{2} = -6.1145 \text{ ft.}$$

The deflections may now be tabulated as in Table 1. Prepare a column for each of the thirteen loads. Write the center deflection, 251.03 ft., under Load 7. The first difference in deflection between Loads 7 and 6 is — 6.1145 ft. The deflections for Loads 6 and 8 are found by adding this quantity to 251.03 ft., giving 244.92 ft. for each.

The second difference now comes into play and should be entered in the same column as the respective loads. There is now in Table 1 the deflections under Loads 6, 7, and 8, the first differences between Loads 6 and 7 and 7 and 8, and the second differences entered in the load columns.

To find the deflection under Load 9, follow the method shown for computing the table of squares, namely, the algebraic sum of the deflection of Load 8 plus the first and second differences will give the deflection under Load 9, thus:

$$244.92 - 6.1145 - 12.229 = 226.57 \text{ ft.,}$$

TABLE 1.—DEFLECTIONS OF LEVEL SPAN.

Load.	1	2	3	4	5	6	7	8	9	10	11	12	13

1st Difference.....		+ 16.995	+ 6.8354	— 3.3242	— 13.4888	— 23.6434	— 33.803	— 43.9626	— 54.1222	— 64.2818	— 74.4414
2d Difference.....	— 10.1596	— 10.1596	— 10.1596	— 10.1596	— 10.1596	— 10.1596	— 10.1596	— 10.1596	— 10.1596	— 10.1596	.....

or, the sum of the first and second difference of Load 7 will be the first difference between Loads 8 and 9. In this case the value is — 18.344 ft. The first difference between the deflections of Loads 9 and 10 will be the sum of the second difference plus the first difference of Loads 8 and 9, namely, — 30.573 ft.

In this manner all the first differences of deflections at the several loads can be computed by addition.

The accuracy of the work may easily be checked by an independent computation for the deflection of any of the loads, preferably the load nearest the support. The formula for the deflection under the load nearest the support is:

$$y = \frac{g\,s\,r}{t}\,[n\,(1 - v) - q\,b] + \frac{w\,s^2\,r}{2\,t}\,(1 - r)$$

in which

$$r = \frac{x}{s} = \frac{m}{s} = v = 0.03125$$

$$y = \frac{1\,150 \times 4\,800 \times 0.03125}{90\,000}\,[13\,(1 - 0.03125) - 6.09375] + 19.04\,(1 - 0.03125)$$

$$= 12.46 + 18.44 = 30.90$$

This checks the value of 30.91 as obtained by the method of differences and shown in Table 1.

As a further illustration of the method, consider the case of an inclined span of 1¾-in. locked-coil cable, listed at 7.3 lb. per ft., as follows:

t = 82 000 lb.
s = 1 720 ft.
g = 4 250 lb.
a = 154.4
n = 11
h = Difference in elevation of supports = — 320 ft., that is, the right support is higher than the left.

The problem is to compute the deflection at the several loads with reference to the left support.

A.—To find the approximate weight of cable per foot of horizontal span:

$$\tan.\ \alpha = \frac{320}{1\,720} = 0.1860$$

$$\alpha = 10^\circ\ 32'$$

$$\sec.\ \alpha = 1.0171$$

Therefore, the horizontal projected weight per foot of cable $= 7.3 \times 1.0171 = 7.42$ lb.

B.—To find second difference:

$$-\frac{a}{t}[g + w\,a] = \frac{154.4}{82\,000}[4\,250 + 7.42 \times 154.4] = -10.1596$$

C.—To find first difference:

$$-\frac{10.1596}{2} \pm \frac{154.4}{1\,720} \times 320 = -5.0798 - 28.7232 = \left\{\begin{matrix} -33.803 \text{ right} \\ -23.6434 \text{ left} \end{matrix}\right\}$$

D.—To find the center deflection, for eleven loads:

$$\frac{g\,s}{4\,t}[11 - 60\,q] + \frac{w\,s^2}{8\,t} - \frac{h}{2} =$$

$$\frac{4\,250 \times 1\,720}{4 \times 82\,000}\left[11 - 60 \times \frac{154.4}{1\,720}\right] + \frac{7.42 \times 1\,720^2}{8 \times 82\,000} - \frac{320}{2} =$$

$$125.1259 + 33.4623 - 160 = -1.4118 \text{ ft.}$$

That is, the cable at the center of the span is 1.41 ft. above the left support.

Table 2 can now be prepared as a table of deflections, as follows: Eleven columns are numbered 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11, respectively. In Column 6 on the line of deflections enter — 1.41. Between Columns 5 and 6 write the first difference, — 23.6434. Between Columns 6 and 7 write the first difference, — 33.803. In all the columns enter the second difference, — 10.1596. The remaining first differences are found by adding or subtracting the constant second difference, — 10.1596, to — 33.803, and the successive sums or differences obtained.

The deflection for Load 7 is found by adding the first difference to the deflection of Load 6, giving — 35.21. The deflection for Load 5 is found by subtracting — 23.6434 from — 1.41, resulting in the deflection of 22.23. The deflection for Load 8 is found as previously indicated, by the sum of the deflection of Load 7, the first and second

differences; thus, — 35.21 — 33.803 — 10.1596 = — 79.18. In like manner, the deflections for Loads 9, 10, and 11 are obtained.

The first difference between Loads 4 and 5 is found by subtracting the second difference from the first difference of Loads 5 and 6, thus, — 23.6434 less — 10.1596 = — 13.4838.

The deflection of Load 5, 22.23, less — 13.4838 gives 35.72, the deflection for Load 4. In a similar manner the deflections for Loads 3, 2, and 1 are computed.

To check the accuracy of the work the deflection of Loads 11 or 1 may be ascertained independently; thus, for Load 1, which is nearest the left support, the deflection is given by the following formula:

$$y = \frac{g\,s\,r}{t}\,[n \times (1 - v) - q\,b] + \frac{w\,s^2\,r}{2\,t}\,(1 - r) - r\,h$$

$$= \frac{4\,250 \times 1\,720 \times 0.05116}{82\,000}\,[11\,(1 - 0.05116) - 60 \times 0.089]$$

$$+ \frac{7.42 \times 1\,720^2 \times 0.05116}{2 \times 82\,000}\,(1 - 0.05116) - 0.05116 \times 320$$

$$= 13.937 + 6.497 - 16.371 = 15.21 \text{ ft.},$$

thereby checking the deflection at Load 1 within 0.01 ft.

DISCUSSION

Mr. Hewitt.

WILLIAM HEWITT,* ESQ. (by letter).—The writer has been impressed by the thorough and exhaustive manner in which this subject has been treated by the author.

A further proof that the second differences of load deflections in a multi-loaded cable are constant and equal to $-\frac{a}{t}(g + w\,a)$ plus the slope factor, is obtained by considering p as a coefficient of the load spacing, a, having any integral value from 0 up to $n - 1$, or a particular value of the independent variable, x, and, differentiating, writing the general formula thus,

$$y = \frac{g}{t\,s}\left[s\,x\,(n-p) - m\,(n\,x - p\,s) - a\,(b\,x - c\,s)\right] + \frac{w\,x}{2\,t}(s - x) + \frac{h\,x}{s}$$

Making $x = m + p\,a$, we have

$$d\,x = d\,(m + p\,a) = d\,p = (m + p\,a) - (m + p\,a - a) = a$$

and

$$d\left[x\,(s - x)\right] = (m + p\,a)\,(s - m - p\,a) -$$

$$(m + p\,a - a)\,(s - m - p\,a - a) = a\left[s - 2\,m - (2\,p - 1)\,a\right].$$

In differentiating with respect to p it should be observed that only such terms can be differentiated as represent values of the independent variable, x, and that $c = \frac{p\,(p-1)}{2}$, not being a factor of x, cannot be differentiated and is to be regarded as a constant. As the sum of the coefficients of x for the load expression,

$$s\,(n - p) - m\,n - a\,b = n\left[s - m - \frac{a}{2}(n - 1)\right] - p\,s,$$

we have, for the first difference,

$$\frac{d\,y}{d\,p} = \frac{g\,a}{t\,s}\left[n\left[s - m - \frac{a}{2}(n-1)\right] - p\,s\right] + \frac{w\,a}{2\,t}\left[s - 2\,m - (2\,p - 1)\,a\right] + \frac{h\,a}{s},$$

and for the second difference,

$$\frac{d^2\,y}{d\,p} = -\frac{a}{t}(g + w\,a),$$

which is constant.

* Trenton, N. J.

Mr. Hewitt.

For loads symmetrically placed,

$$m = \frac{s}{2} - \frac{a}{2}(n-1), \text{ and } \frac{d\,y}{d\,p} = \frac{a\,(g + w\,a)}{2\,t}(n - 2\,p) + \frac{h\,a}{s}.$$

For an odd number of loads,

$$p = \frac{1}{2}(n-1) \text{ and } n - 2\,p = 1, \text{ hence, } \frac{d\,y}{d\,p} = \frac{a}{2\,t}(g + w\,a) + \frac{h\,a}{s}.$$

For an even number of loads,

$$p = \frac{n}{2} - 1 \text{ and } n - 2\,p = 2, \text{ hence, } \frac{d\,y}{d\,p} = \frac{a}{t}(g + w\,a) + \frac{h\,a}{s}.$$

For an odd number of loads, therefore, the first difference is one-half the second plus the slope factor, and for an even number of loads it is equal to the second plus the slope factor.

The writer has had occasion to use this method of determining the load deflections of a cable for a multi-loaded span, and has found it a great saving in time and labor, as compared with the method heretofore used of applying the general formula for each load, and that errors in the computations are less likely to occur. He has also, in a few instances, checked his figures by the application of the general formula, and has obtained the same results, or results with insignificantly small differences.

The discovery by Mr. Carstarphen that the second differences in the deflections of a multi-loaded cable are constant, and can be computed so readily and quickly, is a surprising one, and a unique and remarkable instance of how the application of an apparently complex formula becomes a comparatively simple operation. This discovery the writer regards as an important one and of far-reaching significance, not only in its bearing on suspension-bridge calculations, but also for the long spans of aerial tramways and other multi-loaded cable spans, where the length and position of the cable must be accurately determined.

Mr. Durham.

EDWARD B. DURHAM,* ESQ. (by letter).—The author has presented a scholarly paper on the subject of cable curves and has called attention to an interesting feature of the equation for a loaded cable, namely, that the second differences of the deflections at successive loads are constant. He has also developed a method of utilizing the feature of constant second differences to calculate these deflections.

The writer has treated this subject of cable curves in Section 26 of Peele's "Mining Engineers' Handbook," and has taken up the case of cables with concentrated loads on pages 1557 to 1559 of that "Handbook". He has determined the deflections for any loading by applying the principle of moments to the particular problem and has considered the method more workable than that given by Mr. Carstarphen. The

* Canonsburg, Pa.

Mr. Durham.

exigencies of a handbook required a terse form of discussion, but an elaboration of the subject may be of interest in connection with this paper.

The position of any cable can be determined by the rule that the deflection at any point of the chord for any loading equals the moment of all the vertical forces on one side of that point divided by the horizontal tension of the cable.

Let s = horizontal span;
h = difference in elevation of the supports;
t = horizontal component of the tension;
w = weight per unit length of cable;
g = weight of one concentrated load;
α = angle of inclination of the chord;

l = length of the chord $= \dfrac{s}{\cos \alpha}$, or $s \sec \alpha$;

d = vertical deflection of the cable below the chord;
n = number of loads on the span;
e = spacing of the loads;
o = point on the chord from which the deflection is measured;
b and c = horizontal distances, respectively, from the two ends of the span to the point where deflection is measured, $b + c = s$;
R = reaction at one support; and
M = sum of the moments of the vertical forces on one side of Point o.

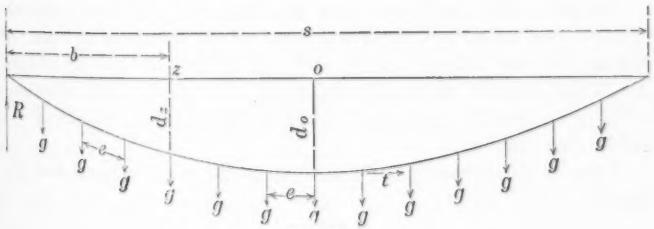

FIG. 3.

Then, in the problem on page 1392, we have (Fig. 3):

$$d = \frac{M}{t},$$

and for the forces to the left of o,

$$M = R\,\frac{s}{2} - g\,(e + 2\,e + 3\,e + 4\,e + 5\,e + 6\,e)\cos\alpha - \frac{w\,l}{2}\,\frac{s}{4}$$

$$R = \frac{w\,l}{2} + \frac{n\,g}{2}$$

Mr. Durham.

then, when, $s = 4\,800$ ft.
$g = 1\,150$ lb.
$t = 90\,000$ lb.
$w = 4.75$ lb.
$e = 375$ ft.
$\alpha = 0$
$h = 0$ ft.
$l = s$.

we have,

$$R = \frac{4.75 \times 4\,800}{2} + \frac{13 \times 1\,150}{2} = 18\,875$$

$$M = 18\,875 \times 2\,400 - 1\,150\,(21 \times 375) - \frac{4.75 \times 4\,800}{2}\,\frac{4\,800}{4}$$

$$= 22\,563\,750$$

$$d = \frac{M}{t} = \frac{22\,563\,750}{90\,000} = 250.71 \text{ ft.}$$

which is close to Mr. Carstarphen's value before correcting for actual length of cable.

Similarly, for another point as z:

$$M = R\,b - g\,(e + 2\,e + 3\,e)\cos\alpha - \frac{w\,b}{\cos\alpha}\,\frac{b}{2}$$

This is applicable to spans with any inclination of chord and with any loading, either uniform or irregular.

For most cable problems, where there are three or more loads uniformly spaced on a span, the calculations can be simplified by using the formula for the deflection of a cable of uniform weight, by making that weight equal to the sum of the actual unit weight of the cable plus a uniformly distributed weight found by dividing the weight of one load by the spacing.

Thus, in the example given previously, the total uniform load per foot is:

$$w_{\text{(total)}} = 4.75 + \frac{1\,150}{375} = 4.75 + 3.067 = 7.817$$

and the deflection at the center of the span is given by

$$d_0 = \frac{w_{\text{(total)}}\,s^2}{8\,t} = \frac{7.817 \times (4\,800)^2}{8 \times 90\,000} = 250.14 \text{ ft.}$$

and at the fourth load from either end by

$$d_z = \frac{b\,c\,w}{2\,t} = \frac{1\,275 \times 3\,525 \times 7.817}{2 \times 90\,000} = 195.$$

Mr. Durham.

Where the span is long and the sag is great, it is desirable to correct the deflections obtained by these methods for the actual length of the cable which may be found by the approximate formula:

$$\text{Length of Cable} = l + \frac{8}{3}\frac{d^2}{l}$$

In the last example, the length

$$= 4\,800 + \frac{8}{3}\frac{250^2}{4\,800} = 4\,834.7 \text{ ft.}$$

The total load on the span and, therefore, the load per foot along the chord, has been increased $\frac{34.7}{4\,800} = 0.724\%$, and, therefore, the deflection will be increased in the same proportion, or:

Deflection at center $= 250.14 \times 1.00724 = 251.96$, and,
Deflection at fourth load $= 195 \times 1.00724 = 196.41$.

These figures are larger than those of Mr. Carstarphen of 251.03 and 196, respectively, as the writer has used the length of the loaded cable and has assumed that the uniform weight on the span due to loading has increased as well as the uniform weight due to the cable.

If the span is inclined, the equation is similar to that given, except that the total load on the span is the length of the inclined chord multiplied by the uniform load per foot and may be written:

$$d_{\text{(at center)}} = \frac{w\,l\,s}{8\,t} = \frac{w\,s^2}{8\,t\cos\alpha}, \text{ and}$$

$$d_{\text{(at any point)}} = \frac{b\,c\,w}{2\,t\cos\alpha}$$

Cable problems like the foregoing usually occur in connection with aerial tramways, and a consideration of their mechanical features will explain the variable and sometimes uncertain character of the initial data and show the necessity of making assumptions to cover some of the conditions.

1.—The tension in the first span is produced by a weight equal to the working tension of the cable. This gives a definite tension in the direction of the tangent to the cable. If the span has an horizontal chord, the tension at the other end of the span will be the same as at the first end, and will be transmitted over the saddle, in the case of a long tramway, to the next span, with a small loss due to the friction on the saddle.

If the first span has an inclined chord and the farther end is higher, the tension at that end will be greater than at the first end; if the farther end is lower, the tension will be less, by an amount equal to the rise or fall multiplied by the unit weight of the cable. This second tension, less the friction on the saddle, becomes the tension

Mr. Durham.

at the beginning of the second span. The tension, t, in the equations is the horizontal component of the tension in the cable at any point and equals the cable tension multiplied by the cosine of the inclination of the tangent to the cable at that point. The exact value of t is, therefore, both unknown and varies from span to span. It is constant for any one span.

In designing a tramway, in order to get a starting point, it is customary to use the working tension of the cable as t and make the layout on that basis, unless it is found that conditions make the tensions in the cable at the end of a span so large as to be unsafe, then the assumed value of t is reduced.

2.—The length of the cable the weight of which produces the sag, is assumed to be equal to the length of the chord, and its weight is assumed to be uniformly distributed along the chord. Neither of these assumptions is exact, but is nearly correct for tramways, as the curves are usually taut and the center deflection is small. The usual formula for the center deflection of a span, *viz.*:

$$d = \frac{w\,l\,s}{8\,t}, \text{ or } \frac{w\,s^2}{8\,t\cos\alpha}$$

where $w\,l$ or, $\frac{w\,s}{\cos\alpha}$, is the total weight on the span, is obtained by taking moments about the center point of the chord, but is based on the previously stated assumptions.

If the span is long or the sag is great, the actual length of the cable may be taken into account.

3.—The loads on a tramway consist of buckets with their contents of freight; these travel on the cable and are spaced and propelled by being gripped to a moving traction rope. They are spaced, therefore, at distances along the cable and are not spaced at uniform horizontal distances, as indicated by the quantity, a, in Mr. Carstarphen's paper, nor at uniform distances along the chord, as assumed by the writer; but the latter assumption is the closer of the two.

As the buckets support the traction rope, on a long span, the weight of each bucket may need to be increased by the weight of a length of traction rope equal to the bucket spacing. On the other hand, the traction rope may be very taut, as occasionally happens, and may tend to lift the buckets and so relieve the cable of part of their weight.

4.—The number of loads on a span can be varied by one and in the operation of a tramway they may occupy an infinite number of positions along the span.

Thus, in the example, which has an horizontal chord, the span, $s = 4\,800$ ft., and the bucket spacing, $e = 375$ ft., assuming that this is also the spacing along the chord, then, $\frac{4\,800}{375} = 12$ spaces $+$ 300 ft.

Mr. Durham.

If one load is at the left-hand saddle, there will be 12 loads on the span and the right-hand load will be 300 ft. from the right-hand saddle. If the loads all move to the right, there will be 13 loads on the span as soon as the load leaves the left-hand saddle, and this number will obtain until they have all moved forward 300 ft. and the right-hand load passes the right-hand saddle. There will then be 12 loads on the span, and this number will obtain while all move forward 75 ft., when another bucket will come on to the left-hand saddle and the initial condition will be restored. During this movement, the cable has been subject to loads in an infinite number of positions and to a variation of one in the number.

Summarizing, the value of t is not known to start with, but is assumed as equal to the working tension of the cable; the weight of the cable and the distribution of the loads are assumed as uniform along the chord, and the number and position of the loads on the span are subject to variation.

In view of these peculiarities of the problems, the writer believes that practical results are obtained by using the total uniformly distributed weight in obtaining the curve where there are at least three loads on the span and these are uniformly spaced. It will be necessary, however, to take the actual loading and solve by using the principle of moments when there are only a few loads on the span or the loads are spaced irregularly. Both these methods of calculating are simple and are easily followed.

Mr. Carstarphen.

F. C. CARSTARPHEN,* M. AM. SOC. C. E. (by letter).—The writer notes with pleasure the comments of Messrs. Hewitt and Durham on his paper dealing with the solution of the multi-loaded cable problem. He appreciates Mr. Hewitt's presentation of a proof of the constancy of the second differences of successive deflections based on the first and second differentials of the modified deflection equation. To many engineers, this proof will appear more elegant than the one presented, based on algebraic subtraction, but it seems that the limits which must be imposed on the value of x of the general deflection formula in order to approach a continuous function of y, and thus permit differentiation to a constant value for the second differential, is more difficult than the proof adopted, unless the reader is more familiar with cable computations than most engineers engaged in general practice.

The writer knows from experience that the method of using the second differences to compute cable deflections is of great practical utility, and hopes that its many advantages will appeal to all who are interested in the solution of problems of this nature. It was thought that the paper presented the subject in a direct and simple manner,

* Trenton, N. J.

Mr. Carstarphen.

but, at this writing, it is not so evident that this aim has been accomplished.

For this reason, the writer is greatly pleased to accept Mr. Hewitt's proof as a strong addition to the argument originally presented, as he is held in high esteem by the Engineering Profession, and has made many contributions to engineering literature. He was associated with the late E. Gybbon Spilsbury, M. Am. Soc. C. E., in developing the manufacture of aerial tramways. It is especially gratifying, therefore, to note Mr. Hewitt's endorsement of the paper as presented, and to learn that he "has found it a great saving in time and labor."

The writer accordingly turns with confidence to a consideration of Mr. Durham's contribution to the discussion. He finds it necessary to declare at once that the paper was not "presented as a scholarly paper on the subject of cable curves," but merely as an explanation of a certain method of computing cable deflections. Mr. Durham appears to make little comment on the paper itself, but offers an apparent defence of some previous exposition of the subject. The writer does not understand the occasion for referring to Peele's "Mining Engineers' Handbook", but it is a pleasure to state that no reflection on it was intended because of the absence of his method from within its covers.

From Mr. Durham's statement that "he has determined the deflections for any loading by applying the principle of moments to the particular problem, and has considered the method more workable than that given by Mr. Carstarphen," it might be inferred that the theory of moments did not enter into the procedure suggested. This, however, is not the case, for it can be readily seen that the formula given on page 1387, namely,

$$y\,t = x\,R_2 - \frac{w\,x^2}{2} - (x-m)\,g - (x-m-a)\,g \ldots [x-m-(p-1)\,a]\,g,$$

is merely the general expression for the particular solution given in Mr. Durham's discussion, that is,

$$M = R\,\frac{s}{2} - g\,(e + 2\,e + 3\,e + 4\,e + 5\,e + 6\,e)\cos\alpha - \frac{w\,l\,s}{8},$$

except that the theory of moments is not correctly applied if the value of the load spacing, e, is to have a variable projected length on the horizontal chord, as illustrated in Fig. 3. It may be stated that the equation,

$$y = \frac{g\,s}{t}\,[(n-p)\,r - v\,(n\,r-p) - q\,(b\,r-c)] + \frac{w\,s^2}{2\,t}\,r\,(1-r) \pm r\,h,$$

is a summation of all the deflections due to the several individual loads of the span, and will be found to be a most efficient means of computing the deflection at any point of a cable supporting a system of loads uniformly spaced.

Mr. Carstarphen.

It follows from this equation that the second differences of the successive deflections are constant, no matter what position the system of loads may have on the span. It is also a "glimpse of the obvious" that if the loads are spaced the constant distance, a, apart on the horizontal chord, they are also equally spaced when referred to any inclined chord; hence the conclusion reached in the paragraph at the bottom of page 1404 is without weight.

When the system of loads supported by the cable occupies one of the several positions indicated in Case I, II, or III, on page 1388, the general formula is greatly modified, and the computation of the center deflection becomes very short and simple, as will be noted in comparing Mr. Durham's solution on page 1402 of the discussion with that given under *C* on page 1393.

It does not appear that any further defence of the utility of the method presented need be offered.

If the computation of deflections by the method of reducing the concentrated to a uniformly distributed load offers results which are sufficiently exact for the purpose at hand, well and good, but it is not as accurate as the formula based on the actual loading.

To illustrate: Suppose the cable span referred to on page 1396 carries five loads spaced horizontally 308.8 (a) ft. apart; what is the center deflection? Solving by the formula of Case I, we have the following:

$$y = \frac{g\,s}{4\,t}(5 - 12\,q) + \frac{w\,s^2}{8\,t} \pm \frac{h}{2}$$

$$= \frac{4\,250 \times 1\,720}{4 \times 82\,000}\left[5 - \frac{308.8}{1\,720}\right] + \frac{7.42 \times 1\,720^2}{8 \times 82\,000} - \frac{320}{2}$$

$$= 63.43 + 33.46 - 160 = -63.11 \text{ ft.},$$

that is, above left support. By uniformly distributed load:

$$\left(\frac{g}{a} + w\right)\frac{s^2}{8\,t} \pm \frac{h}{2}$$

$$= \frac{\left(\frac{4\,250}{308.8} + 7.42\right)1\,720^2}{8 \times 82\,000} = 95.53 - 160 = -64.47 \text{ ft.},$$

above left support, a difference of 1.36 ft.

In so far as the correct deflections may be computed by the method of second differences with the greatest ease for all cases where the number of loads is in excess of three, the writer prefers it to all others.

The remarks concerning the criteria of design for aerial tramways, although of value as an addenda to the section of the Engineers' Handbook previously referred to, do not appear to be germane to the subject-matter of the paper, and accordingly will not be considered here.

Mr. Carstarphen.

For those who are interested in a formula for computing the deflection of a loaded cable when treated as a catenary, the following is presented:

$$y = \frac{g\,s}{t}\left[(n-p)\,r - v\,(n\,r-p) - q\,(b\,r-c)\right]$$

$$+\frac{t}{w}\left[\sinh\frac{w\,x}{t}\sinh\frac{w\,s}{2\,t} - \cosh\frac{w\,s}{2\,t}\left(\cosh\frac{w\,x}{t}-1\right)\right]\sec\alpha \pm r\,h.$$

When the center deflection of a system of loads is under investigation, such as Case I, on page 1388, this formula reduces to:

$$y = \frac{g\,s}{4\,t}\left[n - \frac{n^2-1}{2}\,q\right] + \frac{t}{w}\left[\cosh\frac{w\,s}{2\,t} - 1\right]\sec\alpha \pm \frac{h}{2}$$

where w is the listed weight per foot of cable, and y is the deflection referred to the left-hand support.

TO THE AMERICAN SOCIETY OF CIVIL ENGINEERS:

The Special Committee to Report on Stresses in Railroad Track herewith presents its second progress report.

I.—INTRODUCTION.

1.—Preliminary.—As was stated in the first progress report under date of November 3d, 1917, the Committee has been co-operating with the Special Committee on Stresses in Track appointed by the American Railway Engineering Association since the organization of the Joint Committee on June 3d, 1914. As the Committee of the American Railway Engineering Association consists of the members of the Special Committee of the American Society of Civil Engineers, eighteen in all, and three other members of the American Railway Engineering Association who do not hold membership in the American Society of Civil Engineers, the work, with the authorization given by the two Societies, has been carried on as one committee. This report is presented simultaneously to the two Societies. In recognition of the financial support given the Committee, the report is also being presented to the American Railroad Association.

It was early realized by the Committee that an adequate report on stresses in railroad track must be based largely on experimental data derived from extensive tests on standard railroad track, and that in view of the complexity of the action of track under load and the variability of the conditions to be found in track and load the work of conducting experiments and reducing the data would necessarily require a large amount of time and effort. An important element in the work, which has involved expenditure of time, effort, and money, has been the development of methods of conducting the tests and of devising the instruments and apparatus. It has been recognized from the start that in obtaining data on the action of track under the variable conditions of both track and load, great refinement of method was not possible and it was important to make tests under conditions of railroad service as nearly normal as is possible, utilizing also of course the data of laboratory investigations where conditions would not permit satisfactory experiments in the field.

The first progress report of the Committee was published by the Society in Vol. LXXXII., p. 1191, of the *Transactions,* (1918) and also in the *Proceedings* for January, 1918, p. 55; also in Vol. 19 of the *Proceedings* of the American Railway Engineering Association (1918) and in *Bulletin No. 205* of the Association. In this first report the action of the track as an elastic structure is discussed and a method of analysis for determining the effect of single wheel loads and of combinations of wheel loads is developed; the method of conducting the tests and the nature of the instruments used are described; and the

tests to determine the stresses in rail developed by static loads and moving loads under a variety of conditions of track and load are described and the data discussed. In particular, the results with several types of locomotive running at a variety of speeds on rails of several weights are given in some detail. Track depression and rail profiles under a variety of loadings are presented, and the properties of track as an elastic structure determined for a variety of conditions are reported. The report relates principally to stresses in rail and to the general elastic conditions of the track.

Conditions existing during the war greatly impeded the progress of the work of the Committee, and of course only such work was undertaken as could be done without interference with any activity or agency helpful in the prosecution of the war. Even since the war closed the conditions have been very unfavorable for carrying on experimental work. The limitations relate to both the use of railroad equipment and the supply of assistance for continuous work.

The work reported herein includes the results of tests with one type of freight locomotive and one type of passenger locomotive on the St. Louis-San Francisco Railway to determine stresses in rail in relation to speed and counterbalance effect, and also the results of similar tests with one type of freight locomotive on the Illinois Central Railroad. The report gives the results of tests on the Illinois Central Railroad and the Chicago, Milwaukee and St. Paul Railway to determine the depression of track under given loads and to find the depression and flexure of ties and their action under load for a variety of conditions found in track. The tests conducted in the Laboratory of Applied Mechanics of the University of Illinois with a view of finding the methods and principles involved in the transmission of pressure from one or more ties downward and laterally through ballast materials are reported and an analytical consideration of the transmission of pressure is given. The report is presented under the following headings: Tests to Determine the Effect of Speed and Counterbalance on Stresses in Rail; Track Depressions; Depression, Flexure, and Bearing Pressure of Cross-Ties; and Transmission of Pressures in Ballast.

The Committee is continuing work on the subject assigned to it.

2.—Acknowledgment.—Funds for use in carrying on the work of the Committee have been taken from the contributions made by the United States Steel Corporation, the Bethlehem Steel Company, the Lackawanna Steel Company, and the Cambria Steel Company, acknowledgment of which was made in the first progress report. The Committee wishes to express appreciation of the appropriation of a fund by the American Railroad Association for its use in 1919 and 1920.

The co-operation of railroad companies in furnishing facilities for the test work has itself been a large contribution. The Illinois Central Railroad, A. S. Baldwin, M. Am. Soc. C. E., Vice-President, and F. L.

Thompson, Chief Engineer, gave the use of its tracks and of locomotive, cars, and crews for the tests made north of Champaign, Ill. The St. Louis-San Francisco Railway, F. G. Jonah, M. Am. Soc. C. E., Chief Engineer, and V. K. Hendricks, M. Am. Soc. C. E., Acting Chief Engineer, gave the use of track, locomotives, and crews for the tests made near Springfield, Mo. The Chicago, Milwaukee and St. Paul Railway, C. F. Loweth, M. Am. Soc. C. E., Chief Engineer, gave the use of track, locomotives, cars, and crews for the tests at Deerfield, Ill., and Libertyville, Ill.

War conditions have made it difficult to maintain a corps for the work—all who had formerly been engaged on the work went into war service. Mr. H. R. Thomas, who, as Assistant Engineer of Tests, had been connected with the testing operations from the beginning, was in direct charge of the field work in the tests on the St. Louis-San Francisco Railway, but was soon after called into Government war service. Mr. N. E. Ensign, Associate in Theoretical and Applied Mechanics in the University of Illinois, conducted the field tests on the Illinois Central Railroad and the Chicago, Milwaukee and St. Paul Railway and has rendered important service in the supervision of reducing the data on track depression and tie flexure and in interpreting the results, as well as in other parts of the work. Mr. M. L. Enger, Professor of Mechanics and Hydraulics in the University of Illinois, has been responsible for the experimental work on transmission of pressure in ballast; his previous study of transmission of pressure in granular materials brought to this work an experience which has made it possible to carry out the laboratory investigation on transmission of pressure through ballast so satisfactorily. Credit is given Professor Enger for interpreting the data of the tests with ballast and analyzing the problem; he is chiefly responsible for the chapter on "Transmission of Pressure in Ballast". Mr. E. E. Cress, Assistant Engineer of Tests, since January, 1919, has given very efficient service in the preparation of material for the report and in the study and interpretation of data—his thoroughness, familiarity with details, and keen grasp of the problems have been very helpful. Others have assisted in the work from time to time and all have given loyal and careful service.

The University of Illinois has continued to co-operate in the work by giving the use of laboratory, shop and office facilities and through the service of members of the staff of the Engineering Experiment Station from time to time.

II.—Tests to Determine the Effect of Speed and Counterbalance on Stresses in Rail.

3.—Purpose of Tests.—In the first progress report it was stated that analysis alone can give little real information on the important subject of the effect of speed of locomotive and train in increasing the

stresses in track, and that reliance must be placed upon experimental data to determine the influence which speed exerts in this matter. The increase in stress in rail with increase in speed as found from the tests reported was given in a general way for points at and between the wheels of the six locomotives used in the tests. No detailed study of the effect of speed was made, however, and the conditions of the tests were such that the effect of the counterbalancing of the locomotives was masked or not brought out. For simplicity of test and to avoid the introduction of variables which had no bearing on the problems then under consideration, all the runs in the tests reported were made with the counterweight of the front driver in its lowest position as it passed the middle one of the three instruments placed on one rail. The result of this arrangement was that the counterbalance effect existing differed for the several instruments and for the several wheels, but the stresses found at any wheel were approximately the same as the average stress throughout the revolution of the wheel, though it is probable that for some drivers the values found were somewhat larger than this average and for others somewhat smaller. No systematic variation due to position of counterweight was found in the results.

In pursuance of the programme of the Committee, tests have now been made to find the variation in stress in rail throughout the revolution of the drivers and to attempt to separate in some measure the effect of counterbalance from the effect of speed alone. In doing this, it was thought best to include a type of locomotive in which difficulty has been found in placing the desirable amount of counterweight on the main driver but in which, instead, the deficiency of counterweight has been added to the other drivers, making a badly balanced locomotive. The use of this class of locomotives had caused considerable injury to the rail of the railroad company; these locomotives were thought therefore to be extreme in the effects of speed and counterbalance. The counterbalancing of the other types of locomotives used, the Pacific and the Mikado types, is not so difficult a problem in design. The use of the Mikado type locomotive also permitted the tests to be connected up with the tests previously made on the Illinois Central Railroad.

The tests were conducted in the manner described in the first progress report for moving-load tests, the strains in the rail being measured with the stremmatograph.

4.—*The Problem of Counterbalancing the Locomotive.*—No attempt is made in this report to go far into the analytical side of the problem of the counterbalance and its effect on track. A brief review of the method of calculation commonly used and of the terms herein employed may be of advantage to the reader. To treat the matter in a thorough manner would involve long and complicated mathematical analyses and examples and would require the discussion of a number of elements on which there seems not to be agreement.

The moving driving parts of a locomotive are usually divided into (*a*) reciprocating parts and (*b*) rotating parts. The reciprocating parts include the piston and piston rod, cross-head, and a portion of the main rod (connecting rod). The rotating parts include crank pins, crank-pin hubs, side rods, the portion of the main rod considered to contribute to rotational effects, etc. The motion of these reciprocating and rotating parts produces a dynamic effect on the locomotive and track, and in designing the locomotive, the attempt is made to counterbalance in such a way as to reduce the dynamic effect, as far as may seem practicable, by adding a counterbalancing weight to the drivers at a location opposite the crank pin.

To help in clearness of expression, the following distinction between counterweight and counterbalance will be made in this report. Counterweight will be used as the weight applied or added to the driver at a point opposite the crank pin for the purpose of balancing or helping to balance the rotating and reciprocating parts. The terms underbalance and overbalance will be used for the deficiency and the excess, respectively, of the counterweight as compared with that necessary to balance the rotating parts or to balance the rotating and reciprocating parts. The term counterbalance will be used to indicate the general condition of underbalance or overbalance as it exists in a given driver. The term counterbalancing will be applied to the general problem of endeavoring to balance the rotating and reciprocating parts.

The vertical effect of a lack of balance of the rotating parts is to increase or decrease the pressure of the drivers on the rails and to vary the pressure upward on the equalizer bars and the frame of the locomotive. A lack of balance for the reciprocating parts has little direct effect on the vertical pressures on the rail at the high and low position of the counterweight, though due to the acceleration of the piston and cross-head it may have a modifying influence on the main driver in certain portions of the revolution of the driver. A lack of balance for the combination of reciprocating and rotating parts produces strains in the locomotive frame and horizontal movements of the locomotive such as nosing. Underbalance and overbalance produce similar effects. It is evident that the counterbalance cannot be made to produce both the minimum vertical effect and the minimum horizontal effect. The methods in use attempt to compromise between the two. The practice in locomotive design is to counterbalance for all rotating parts and for a portion of the reciprocating parts, the proportion of the latter varying from one-half to two-thirds. It is evident, then, that so far as vertical pressure on track is concerned, this practice results in general in overbalancing the rotating parts.

In some types of locomotive other difficulties are found. The diameter of the driver may be so small and the weights of the rotating and reciprocating parts so great that there is not space on the main driver

to place the necessary counterweight even if lead is used for the purpose. In such cases it is the practice to place as much counterweight on the main driver as practicable and to make up the deficiency by placing an extra amount of counterweight on the other drivers, dividing this amount equally among these drivers. The result is that the main driver may be underbalanced even for the rotating parts and the other drivers will have their overbalance for rotating parts increased. The effect on the track structure may be very marked, even though the effect on the locomotive itself may not be noticeable.

Another counterbalancing device sometimes used in such a type of locomotive is a counterweight, known as a bob, which is attached to the driver axle inside the bearings. On account of limitations of space in the design of frame commonly used, the radius of rotation of the bob is relatively small, and its weight must be correspondingly large, thus adding to the driver load at low speeds.

The vertical or horizontal pressure developed by the unbalanced rotating and reciprocating parts is called the dynamic augment. This dynamic augment is, of course, a function of the speed, increasing as the square of the speed.

The formula generally used for calculating the dynamic augment is the formula for centrifugal force,

$$C = \frac{W v^2}{g r} \qquad (12)^*$$

in which

W = the weight of the rotating or reciprocating part for which the dynamic augment is desired, or the unbalanced part of the rotating parts in case the resulting rotational effect is wanted;
g = the acceleration of gravity;
v = the rotational velocity or speed of the part;
r = the radius of the circle taken by the center of gravity of the rotating part.

It is convenient to transfer all weights to the equivalent weight at the center of the crank pin and to use the radius of the circle taken by the center of the crank pin relatively to the center of the driver.

The equation implies consistent units, and the values may be taken in pounds, feet, and seconds, with g as 32.2 ft. per sec. per sec. If V is the speed of the locomotive in miles per hour, the speed in feet per second will be $\frac{4.4}{3} V$. The rotational speed of the crank pin v is obtained by multiplying this by the ratio of the radius of the crank-pin circle r

* This equation number follows the last number used in the first Progress Report, *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1206.

to one-half the diameter of the driver. The distance of the counterweight from the center of the driver will be greater than the radius of the crank-pin circle, and a weight of equivalent rotational effect for a radius r may be used, the equivalent weight being found by multiplying the counterweight by the ratio of the rotational radius of the center of the counterweight to that of the crank pin. For determining the vertical dynamic augment, W should include the excess or deficiency of the rotating parts, and should not include the reciprocating parts, a portion of the main rod being taken as a rotating part. The part of the weight of the main rod which should be considered as an equivalent rotating weight at the crank pin may be determined by the principles of mechanics.

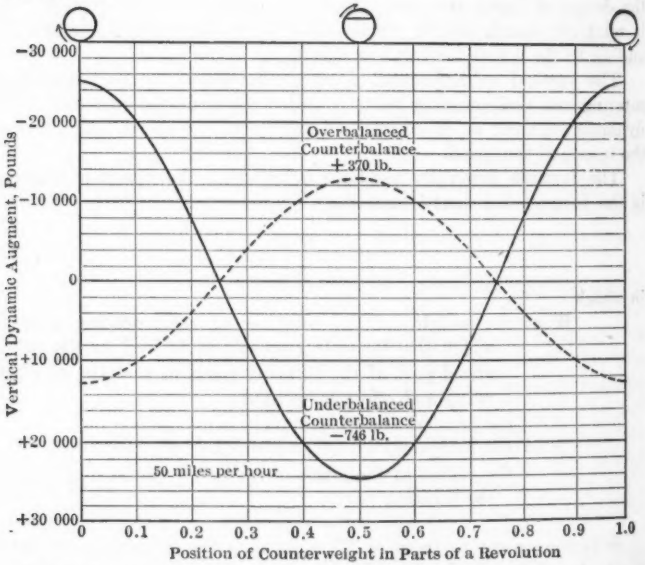

FIG. 1.—VERTICAL COMPONENT OF DYNAMIC AUGMENT FOR OVERBALANCE AND UNDERBALANCE OF ROTATING PARTS.

For determining the horizontal dynamic augment, the weight of the reciprocating parts should be included in determining the unbalanced weight W. In making the calculations, the center of gravity of the rotating part is used in getting the radius of rotation.

Fig. 1 gives, through a complete revolution, the values of the vertical component of the dynamic augment for an underbalance of 746 lb. at the crank-pin circle and also for an overbalance of 370 lb. at the crank-pin circle for a speed of 50 miles per hour, the diameter

of the driver being 60 in. and the radius of the crank-pin circle being one-half the radius of the driver. For the counterweights at one-fourth of a revolution from the low position (90°) the vertical dynamic augment for both underbalance and overbalance is zero, as is that at three-fourths of a revolution (270°). The position giving the maximum downward pressure of an underbalanced counterweight gives the maximum upward pressure of an overbalanced counterweight.

The fact that the center of gravity of the rods and other rotating parts is not in the same vertical plane as the counterweight or the rail is not usually taken into account. The disturbing forces are said to be slight in comparison with the principal rotating and reciprocating forces. The following shows that this element of the problem may need attention.

The plane of rotation of the side rod is some distance outside the plane of the counterweight, the main rod is still farther away, and the part of the pin passing through these rods is also well outside the driver. The result of this eccentricity of position is to increase the effect of the dynamic augment at the central plane of the counterweight, and to require a greater amount of counterweight than would be necessary if these parts and the counterweight were in the same plane. The amount of this increase, in terms of the dynamic augment calculated by the formula given for dynamic augment, is determined by the ratio of the horizontal distance between the center of the counterweight and the center of the rod or other rotating part to the horizontal distance between the centers of the companion drivers. For the locomotives of the three types used in the tests herein reported—the Santa Fe, Pacific, and Mikado—this ratio, found from the dimensions of the parts, averaged about 0.11 for the side rod and the part of the pin within the side rod, and 0.23 for the main rod and the part of the pin within the main rod; that is, the vertical dynamic augment effect at the vertical plane through the center of the counterweight produced by the rotating parts outside of the driver, is 11% greater in the case of the side rod and its part of the pin, and 23% greater in the case of the main rod and its pin, than will exist at the plane of these rods as found by the formula for dynamic augment and centrifugal force. The value of the dynamic augment of these rods and pin calculated by the usual formula must then be increased in the proportion of 11% for the side rod and 23% for the main rod, or the weights of these parts may be considered to be that much larger in determining the underbalance or overbalance.

For the main driver the effect so found is considerable, affecting the amount of counterweight required; a seeming overbalance for rotating parts as judged by the method of calculation generally used in design may become an underbalanced wheel, while for an underbalanced main driver the deficiency in counterweight may be considerably greater than

that found when this eccentricity of position is not taken into account. For drivers other than the main driver the effect is much smaller and may not need consideration.

The foregoing discussion takes the dynamic augment back to the center of the counterweight; the center of the counterweight in locomotives of the types used is generally outside the center of the rail and the point of contact between wheel and rail, and the effect of this is to increase by a small amount the resulting pressure on the rail due to overbalance or underbalance; in the cases under consideration this would probably not increase the dynamic augment by more than 3 per cent. It must be concluded, however, that the location of the rods away from the plane of the counterweight may become of importance in the calculations of the counterbalance of the main driver and should not be overlooked.

The effect due to the rods and the counterweight of a given driver not being in the same plane with one another extends also to the companion driver on the other rail, decreasing the vertical pressure of the companion driver when the pin of the other driver is down and increasing it when the pin is up. It will be seen that the effect upon the companion driver comes at a point in its revolution which is away from the maximum and minimum effect of its own counterbalancing, and hence this element of the problem may not particularly affect the value of the maximum pressure developed by the driver. In case a main driver is balanced for its own masses only, the effect of the rods on its companion driver will be to put it out of balance.

A further condition complicates the problem: the crank pins of the left side of the locomotive are set 90° behind those on the right side. This adds to the stresses in the locomotive and may be expected to produce lateral bending in rails.

In judging of the vertical rail pressure produced by partially balanced rotating parts or by overbalanced rotating parts, it may be sufficiently near the truth to consider that the vertical dynamic augment produced by the excess or deficiency of counterbalance of the rotating parts acts as a vertical pressure on the rail at each driver. This may be expected to be approximately true even when the adjacent drivers have quite different dynamic augment, since the change in depression of the track structure due to the added or decreased pressure on the rail, is small in comparison with the total amount of deflection of the locomotive spring produced by the weight of the locomotive tributary to the given driver, and hence a movement of the wheel downward with the increase in track depression produced by the dynamic augment will result in reducing the load transmitted from the locomotive frame only a relatively small amount and the action of the equalizing levers may be expected to minimize even this effect. It seems proper, then, in making calculations, to consider the vertical dynamic augment of

each driver as being separate downward or upward loads which may be added algebraically to the individual driver loads on the rail. How much this will be modified by the spring of rail and movements of locomotive springs and how much will be transmitted to other wheels by the equalizing levers cannot well be determined by analysis.

Having calculated the vertical dynamic augment of the rotating parts (using the underbalance or the overbalance), the vertical pressures so obtained may be used as positive or negative loads at the wheel points, and calculations for stress in rail may be made for such loads by the methods given in the first progress report of the Committee under "Combination of Wheel Loads".* Illustrations of the use of this method in the calculation of resulting loads and stresses may be found in the discussion of test results which follows.

As the tests for effect of counterbalance were made with the locomotive running with steam shut off, the effect of cylinder pressure does not enter into the results discussed except so far as there may have been resisting pressure developed in the cylinders. For locomotives working under steam pressure, the effect is to increase the downward pressure of the main driver by the vertical component of the main rod tension or compression. For the dimensions of the main rod in the locomotives used this vertical pressure at the up and down points of the crank pin would be from 0.10 to 0.14 of the cylinder pressure at mid-stroke, this vertical pressure presumably being all taken by the main driver.

5.—The Locomotives.—In the tests on the St. Louis-San Francisco Railway two types of locomotives were used, the Santa Fe type of freight locomotive and the Pacific 1060 type of passenger locomotive. Slight variations were made in the locomotives by lightening the reciprocating and rotating parts of the Santa Fe and Pacific types and by changing the position of the equalizer pin of the Pacific type. The locomotives of the Santa Fe type were new, having been in service less than a year. The Pacific type locomotives had been in service about two years.

Fig. 2 gives the spacing of drivers and the wheel loads. The diameter of the drivers in the Santa Fe type was 60 in. and that in the Pacific type 73 in. The crank pin was 15 in. from the center of driver in the Santa Fe type, and 14 in. in the Pacific. The corresponding distance for center of counterweight was 16½ in. in the Santa Fe type and 20¼ in. for the main driver and 25¼ in. for the other two drivers in the Pacific type.

In Table 1 are found the weights of the reciprocating and rotating parts of the Santa Fe locomotive as given by the Mechanical Department of the St. Louis-San Francisco Railway, together with the calculated required counterweights, the amount of counterweight used and

* *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1208.

the excess or deficiency of counterbalance by the method of calculation used by the Railroad Company. It will be noted that 60% of the weight of the reciprocating parts is included in the counterbalancing calculations and that this weight is divided among four drivers and not among all five, a matter which affects the vertical dynamic augment only as the overbalance or underbalance of the several wheels for rotational parts is affected. Table 1 also gives the excess or deficiency of counterweight needed to balance the rotating parts only, since this excess or deficiency is the principal factor affecting increase or decrease in vertical pressure on the rail.

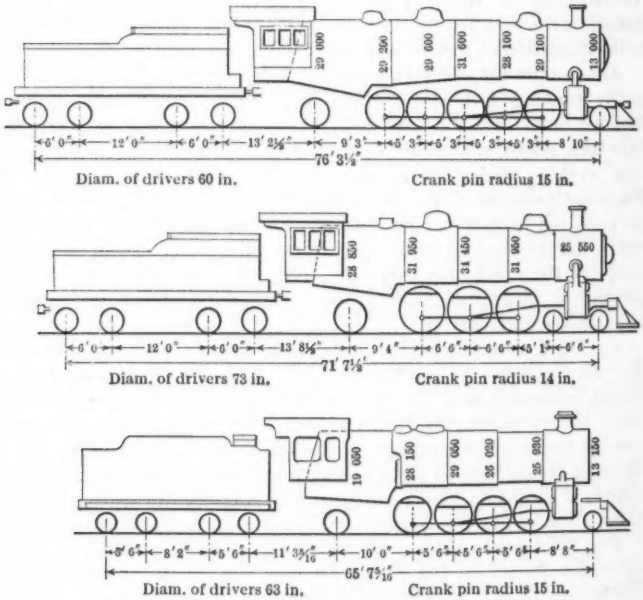

FIG. 2.—DIAGRAMS OF THE THREE TYPES OF LOCOMOTIVES.

There may be of course some question concerning the amount or proportion of the weight of the main rod which contributes to the rotational effect. The excess or deficiency of counterweight needed to balance the rotating parts only, as given in Table 1, is the value usually considered in designing practice, and is found without taking into consideration the effect of the rods and pin not being in the same vertical plane with the counterweight of the driver. The method outlined in the preceding article for taking this variation of position

Crank-pin hub	189	196	305	196	189
One-half eccentric crank	.....	.....	60	.....	.....
Total	882	1 289	2 260	1 210	867
Equivalent weight required at center of counterweight, average taken for two corresponding wheels	794	1 135	2 054	1 135	794
Weight used	812	1 156	1 376	1 156	812
Difference between weight required and weight obtained	+ 18	+ 20	− 678	+ 20	+ 18
Equivalent difference at crank-pin circle	+ 20	+ 22	− 746	+ 22	+ 20
Overbalance or underbalance at crank-pin circle for rotating parts only	+ 368	+ 370	− 746*	+ 370	+ 368

* This becomes 1 042 lb. if the effect of the rods and pin not being in the plane of the counterweight is considered to be as described in the text.

of the dynamic forces into account involved adding to the weight of the side rod and its part of the pin 11% of the weight of these parts as being approximately the effect for the average of the dimensions of the three types of locomotives used in the tests, and to the weight of the main rod used and its part of the pin 23% of the weight of these parts—this increased weight being considered to represent the weight to be used in determining the condition of counterbalance in the plane of the counterweight. Applying these percentages to the parts affecting the main driver, the weight of the main rod coming on the crank pin and that of the side rod and also the parts of the crank pin in the main rod and the side rod, the underbalance of the main driver is found to be 1042 lb. instead of 746 lb.—a very great deficiency. For the other drivers the effect is not so great; there is a reduction in the amount of overbalance of 27 lb. for Drivers 1 and 5 and of 67 lb. for Drivers 2 and 4. It is not known how closely the weights of the locomotives used agree with the weights given in Table 1; the indications are that there are uncertainties in the weights and in their positions.

In Table 2 are given in the same way the weights of the reciprocating and rotating parts of the Pacific type locomotive as furnished by the Mechanical Department of the St. Louis-San Francisco Railway.

TABLE 2.—Weights of Rotating and Reciprocating Parts, in Pounds—Pacific Type Locomotive of the St. Louis-San Francisco Railway.

Reciprocating Parts.

One-half eccentric crank	.....	60	.....
Total	1 004	2 474	998
Equivalent weight required at center of counterweight, average taken for corresponding wheels	555	1 710	555
Weight used	525	1 605	522
Difference between weight required and weight obtained	— 30	— 105	— 33
Equivalent difference at crank-pin circle	— 54	— 152	— 59
Overbalance or underbalance at crank-pin circle for rotating parts only	+ 428	+ 330*	+ 423

* This becomes 76 lb. if the effect of the rods and pin not being in the plane of the counterweight is considered to be as described in the text.

Applying the method already outlined for obtaining the effect of the main rod and side rod at the plane of the counterweight by means of the factors found from the dimensions of the driver and rods, as just used for the main driver of the Santa Fe type locomotive, it will be found that instead of an overbalance of 330 lb. for the main driver, as given in Table 2, there will be an overbalance of 76 lb., or in effect nearly a balanced condition. The results of the tests indicate an underbalance in the main driver. There appears to be an uncertainty in regard to the accuracy of some of the weights given in this table. It should be noted that the effect upon the counterbalance calculations for the first and third drivers due to the plane of the side rod not being in the plane of the driver is not large, and the error due to neglecting this element is inconsiderable. It may be noted that the larger diameter of the driver of the Pacific locomotive makes the problem of counterbalance easier than for the Santa Fe type even at speeds considerably higher than the freight locomotive would be expected to take.

Fig. 2 also gives the spacing of drivers and the wheel loads of the Mikado locomotive of the Illinois Central Railroad. The diameter of the drivers was nominally 63 in., but the measured circumference was 195 in. Table 3 gives the weights of the rotating parts of the Mikado

locomotives as furnished by the Illinois Central Railroad. Here the consideration of the planes in which the parts rotate reduces the overbalance for rotating parts given for the main driver to what would appear to be an approximate balance. The results of the tests will be found to indicate an underbalance for the main driver instead of a balance or an overbalance.

TABLE 3.—WEIGHTS OF ROTATING PARTS, IN POUNDS—MIKADO TYPE LOCOMOTIVE OF THE ILLINOIS CENTRAL RAILROAD.

Driver number	4	Main	2	1
60% of weight of reciprocating parts	263	263	263	263
Main rod, weight on crank pin	.....	630	.....	.....
Side rod, weight on crank pin	145	829	480	154
Total weight considered	408	1 722	743	417
Equivalent counterbalance weight at crank pin in excess of that required to balance crank pin and crank-pin hub.	408	1 722	743	417
Overbalance at crank-pin circle for rotating parts only	+ 263	+ 263*	+ 263	+ 263

* This becomes an underbalance of 15 lb. if the effect of the rods and pin being in the plane of the counterweight is considered to be as described in the text.

It may be of interest to note that the dynamic argument for each pound of underbalance or overbalance considered to be concentrated at the crank pin for the three locomotives used amounts to 33.4 lb. for the Santa Fe type locomotive at a speed of 50 miles per hour, 30.3 lb. for the Pacific type at 60 miles per hour, and 24.5 lb. for the Mikado type at 45 miles per hour; for example, an underbalance of 746 lb. on the Santa Fe type gives a dynamic augment of 24 900 lb.

In all the tests the locomotives were considered to be in good condition. Tires were not worn, except for the main driver of the Santa Fe type (without flanges) which showed more or less wear. The locomotives were representative of those of the same class used on the two railroads.

6.—The Track.—The tests on the St. Louis-San Francisco Railway, made November 20th to December 7th, 1917, were conducted on a section of single track about three miles west of Springfield, Mo. The rail was 85-lb., Am. Soc. C. E. section, rolled in October, 1906. The rail section as worn (shown in Fig. 3) had a moment of inertia (I) of 29.1 in.^{4} about a horizontal axis, and of 6.8 in.^{4} about a vertical axis. The section modulus $\left(\frac{I}{c}\right)$ was 12.0 in.^{3} about a horizontal axis and 2.6 in.^{3} about a vertical axis. The ties were 6 by 8 in. by 8 ft., of oak, spaced about 20 in. apart, center to center, twenty to a 33-ft. rail length. There were 15 in. of chats ballast of good quality. The track was in fair surface and alignment, and was used as it was found. It had not been tamped recently, but as freight trains are not run over this stretch of track the effect of traffic is not great.

The tests on the Illinois Central Railroad were conducted two miles north of Champaign, Ill., September 19th to 21st, 1918, on the southbound track used in the earlier tests reported in the first progress report of the Committee (see page 1237* of the first progress report), the location being that described as Section B. The rail was 85-lb., Am. Soc. C. E. section, laid in 1902. The rail section is given in Fig. 3. The properties used in the calculations were the same as those given in the first progress report, 27.0 in.^{4} for the moment of inertia about the horizontal axis and 11.1 in.^{3} for the section modulus for the remote fiber at the base of rail. The ties were the 6 by 8-in. by 8-ft., oak ties which had been specially prepared for this stretch of track. They were spaced approximately 20 in. apart, 20 ties to a 33-ft. rail. On the section used in the test there was 12 in. of stone ballast. The track had not been tamped for some time and was not in the best condition of line and surface, but it was used in the condition found.

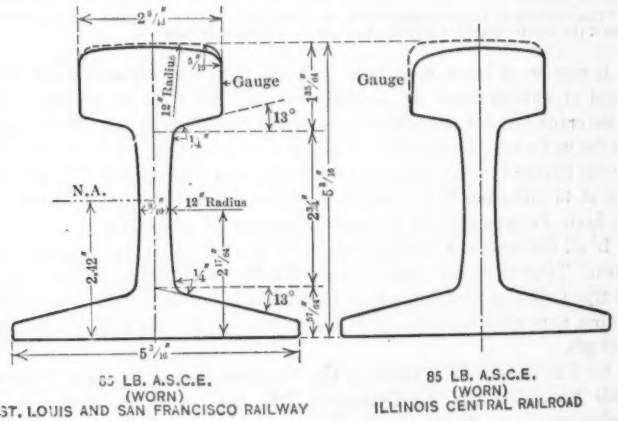

FIG. 3.—SECTIONS OF RAILS USED IN TESTS.

7.—*The Conduct of the Tests.*—The instruments used to determine the strains in the rail were the stremmatographs described in the first progress report, page 1224.* Four stremmatographs were used simultaneously. The methods used were generally the same as those described in the previous progress report. Fig. 4 shows the position of the instruments as used in the tests on the St. Louis-San Francisco Railway. Set-ups *a*, *c*, and *d* were on the same rail, and Set-ups *b* and *e* were on the adjacent rail. It will be noted that in two set-ups, three instruments were on the rail on one side of the track and the fourth

* *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918).

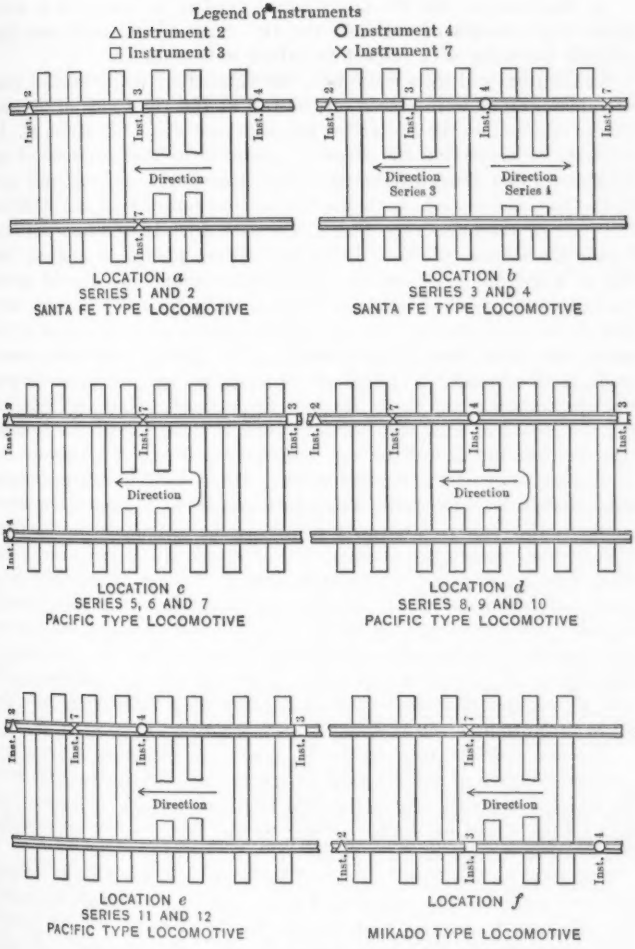

FIG. 4.—POSITION OF STREMMATOGRAPHS IN TESTS.

was on the rail of the opposite side. The instruments were spaced two, three, and four tie spaces apart.

In the tests on the St. Louis-San Francisco Railway, as it was a single-track stretch of railroad, the two sides of the track were presumably the same with respect to ballast and tamping.

In the principal tests made with the Santa Fe type locomotive, three stremmatographs were placed on the rail at the right side of the locomotive and one on the rail at the left side (see Fig. 4, Location *a*). In the tests to determine the stresses developed at the two sides of the locomotive, the four instruments were placed on one rail, and part of the tests were made with the locomotive running in one direction and part in the other (see Fig. 4, Location *b*). In the tests with the Pacific locomotive, the four instruments were placed on one rail (see Fig. 4, Locations *c*, *d*, and *e*). In all runs steam was shut off as the locomotive approached the test section of track. The speeds were read from a speedometer in the cab connected with the tread of the trailer, the instrument being checked up by timing runs over a measured length of track. For each set of tests the order of speeds for consecutive runs was the same, three or four speeds being used together, and the record of each three or four runs at these speeds was made on one set of disks; new disks were then placed in the instruments.

The position of the counterweight with respect to one instrument was observed for each run. The effort was made to keep the counterweight at the same position with respect to the instrument for the three or four runs covering the three or four speeds used, and then to slip the drivers sufficiently to change the position of the counterweight about one-fourth of a revolution. The slipping of the drivers in stopping and starting, however, changed the position somewhat. The instruments were placed about one driver diameter apart so that for each instrument there was a different position of counterweight. Altogether the tests give a general distribution of position of counterweight over the entire revolution.

The extent of the tests on the St. Louis-San Francisco Railway was limited by reason of the difficulty in sparing the locomotives from service, the demands of traffic at the time being very great. A larger number of runs would have added much to the value of the information. The weather conditions were unfavorable much of the time.

The tests on the Illinois Central Railroad with the Mikado locomotive were made on the south-bound track, and in order to get the necessary distance to acquire high speeds, the locomotive was run northward. Three stremmatographs were placed on the west rail (left side of the locomotive) and one on the east rail opposite the middle one of the instruments. The arrangement is shown at *f* in Fig. 4. The three instruments on the one rail were placed about 63 in. apart, nearly one-third the circumference of a driver.

It should be noted that the rail on which these three instruments were placed was on the outer side of the double track and that, as is shown in the report of the tests on track depression, this side of the track was not in as good surface condition as the inner side. The order of the speeds was 5, 35, 25, and 45 miles per hour, and the four consecutive runs were recorded on the same disks. In all runs steam was shut off as the locomotive approached the test section of track. As with the other tests, the demand of traffic for locomotives was such as to limit the work of the tests. The data secured seem sufficient for general purposes; more tests would have given a wider range of information.

8.—Reduction of Data.—The process followed in the reduction of the data obtained by the stremmatographs in the moving load tests was the same as that which was described in the first progress report. The stremmatograph records were read with a microscope fitted with a micrometer eyepiece. Readings were taken for points in the record corresponding to the position of wheel over instrument and to a point between wheels. In reducing these measurements the readings were multiplied by the proper microscopic constant and then reduced to stresses by multiplying by a constant which involves the value of the moment of inertia and the position of the vertical axis of the rail section, the vertical distance of the needle-bar below the base of rail, the modulus of elasticity of steel (taken as 30 000 000 lb. per sq. in.), and the gauge length (which was 4 in.). A correction was also made to allow for the variation of moment and stress over the gauge length. To obtain the maximum stress at the middle of the gauge length the average stress over the gauge length for points corresponding to the position of wheel over instrument was multiplied by the factor 1.04, as was done with the tests recorded in the first progress report, so that the stresses reported at points of positive moment are stresses in pounds per square inch at the base of the rail at the middle of the gauge length. The variation over the gauge length at points of negative moment was slight and no correction was used for the stresses at such points.

In general, the readings of the two disks of an instrument, giving stresses on two sides of the rail, were averaged and the average was taken as the observation for that instrument for the given run for the given position of wheel. In case the record on one disk of an instrument was defective and that on the companion disk was clear, the one good record was generally also discarded. In case the record of a disk was clear enough to be usable, the record for all the wheels and all the runs on the disk was usually measureable, although the line made by the truck and trailer was less definite than that made by the drivers. Sometimes, however, not all of the record on a disk was clear; in this case the portion available was used. For some of the tests nearly one-

third of the records had to be discarded. It appears that the disk readings taken with the Santa Fe type locomotive were generally clearer than those taken with the Pacific type. The conditions of the tests on the Illinois Central were more favorable and the records were generally good. The records at points of negative moment were generally less clear than those at the wheels, and a larger proportion was discarded.

For any reading or observation, the position of the counterweight of the driver corresponding to the point in the record was found in terms of the part of a revolution of the driver beyond the last down position of the counterweight. This was done for each driver and also for trailer and front truck. In the reduction, the high point of the record was assumed to have been made when the wheel was directly over the instrument.

The readings of the stremmatograph records, the reduction of the data, and the location of the counterweight with respect to each instrument and each point in the record involved a large amount of work, as nearly 100 000 readings were made.

The accuracy of the records and their reduction is considered to be as good as that of the stremmatograph data reported in the first progress report.

It may be noted that for the rail used in the tests on both the St. Louis-San Francisco Railway and Illinois Central Railroad the stress at the extreme fiber of the head of rail is about 10% greater than that in the extreme fiber at the base of rail. The latter has been used in giving results because the width of the base of rail makes the stresses due to lateral bending greater there than in the head of the rail and the lateral bending stresses are great enough to be significant.

9.—Tests on St. Louis-San Francisco Railway.—Table 4 gives information on Series 1 to 12 made on the St. Louis-San Francisco Railway. The injury done to rails by the Santa Fe locomotives soon after they were received from the builders had given the Railroad Company some concern, and the opportunity was taken to make tests with what was evidently a poorly balanced locomotive. The weight on the trailer of the Pacific locomotive seemed excessive, and for a wheel well away from other wheels the stress developed in the rail would be expected to be high. The bearing of the trailer at times had run hot. The tests were made to obtain information on the effect of speed and counterbalance with this type of passenger locomotive.

In Series 1, the order of runs in the tests was 5, 25, and 40 miles per hour for Locomotive No. 22, and 25, 50, 25, and 50 miles per hour for Locomotive No. 28. For Series 2, two sets were run—the first at 5, 25, and 40 and the second at 25, 50, 25, and 50 miles per hour. In Series 3 and 4 the order 5, 25, and 40 was used. For all series with the Pacific type locomotive, the order was 5, 45, and 60 miles per hour.

12	" "	" ...	1067	Rear hole.....	" "

The tests were not made in the order of the numbers of the series; instead, the locomotives were taken as the demands of traffic or matters of convenience permitted. In the discussion which follows the series are grouped for the consideration of effect of speed and counterbalance, effect of lightening rotating parts, stress under the two sides of the locomotive, and general comparisons.

10.—The Santa Fe Type Locomotive; Effect of Speed and Counterbalance.—The typical effect of the combination of speed and counterbalance upon stresses in rail for Series 1 with the Santa Fe type locomotives is shown in Fig. 5, which gives sample curves for the main driver taken from the plotted results of the tests with the Santa Fe type locomotive from the data of the instruments on the rail on the right side of the locomotive only. The ordinates of the diagram represent stresses at the base of the rail in pounds per square inch. The abscissas represent the position of the counterweight at the time the wheel passed over the instrument with respect to its down position, the scale being in fractions of a complete revolution of the wheel. The curves represent the average of the results of the several runs at each speed. For a speed of 5 miles per hour the values are represented by a straight line, since the variation from it is small. As the driver is underbalanced, in general the greatest stress in the rail is developed when the counterweight is at its high position. At a speed of 50 miles per hour, it is noted that the maximum value of the curve is 44 700 lb. per sq. in. and the minimum value 14 000 lb. per sq. in. The line marked "mean value of 50 miles per hour curve" is the average ordinate of the curve. The variation above and below this line may be considered to be due largely to the lack of balance of the rotating parts.

The difference between the mean value of the stress found from the curve for 50 miles per hour and the stress at 5 miles per hour may be considered to be largely the effect of speed without reference to effect of rotating parts (quite frequently called impact effect or speed effect), though part may be due to lack of balance of rotating parts. The dotted line of Fig. 5 was obtained by the use of the common formula for the vertical pressure of a rotating part, the calculation here being modified to touch the curve for 50 miles per hour at its high and low points. It will be noted that the form of the observed curves is more pointed than is the curve calculated by analytical methods, and also that

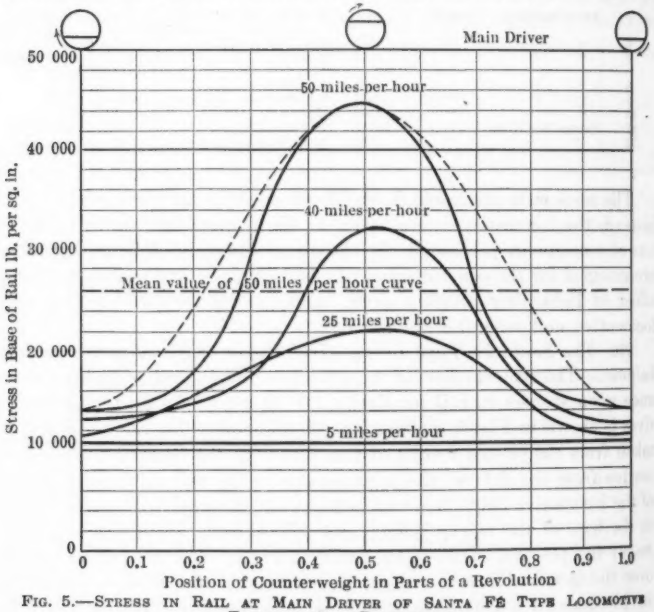

FIG. 5.—STRESS IN RAIL AT MAIN DRIVER OF SANTA FÉ TYPE LOCOMOTIVE THROUGHOUT A REVOLUTION.

the mean value of the curve is generally below the median point of the curve. These differences are characteristic of many of the tests, though it appears that there are as many cases where the observed curve is less pointed than the analytical curve, as for more pointed curves.

As examples of the test data, the test results for Series 1 with the Santa Fe type locomotive for four speeds for the main driver and Driver No. 4, and for one speed for the other drivers and the trailer are plotted in Figs. 6 to 11. Results given by the several instruments are indicated by individual symbols, which are explained in Fig. 4. The curves representing the stress for a given speed throughout an entire revolution

were formed by first averaging the values of the plotted points in groups for each twentieth of a revolution and then drawing a curve to represent as well as possible the position and trend of these points. As in this series there were more runs at 25 miles per hour and less at 50 miles per hour than at the other speeds, the data points for a speed of 25 miles per hour are most numerous, and those for 50 miles per hour the least numerous, the number at the latter speed being only about half that at 5 miles per hour or 40 miles per hour. As may be expected, at a speed of 5 miles per hour the variation in stress due to other causes is so much greater than that due to effect of counterbalance as to mask any effect of counterbalance, and accordingly a straight-line average of all the points has been used for all the wheels for the speed of 5 miles per hour. In each case a line has been drawn above the average curve and one below it which together form the limits of a belt which includes most of the observed points. The distribution of these points vertically over the belt generally is fairly uniform when there are fifty or more points in the diagram. In some cases, with insufficiency of data, the points are quite scattered. The line representing the average ordinate for the curves is marked "mean value of curve"; the line representing the average stress at 5 miles per hour has also been drawn. The diagrams include the results for the instrument on the left rail, although as shown in Article 12 on "Comparison of Stresses under the Two Sides of the Santa Fe Type Locomotive", the stresses in rail on the two sides of the locomotive differed considerably.

Fig. 12 gives the stress in base of rail throughout a revolution of driver for all the drivers and the trailer for Series 1, obtained as described in the preceding paragraph. These curves then represent the average stress for any given position of counterweight. It should be borne in mind that the observed points are not always well distributed in the plots from which these average curves were formed (such as are shown in Fig. 9) and in some cases there is indefiniteness in the data, which makes the forming of the curve difficult and somewhat uncertain. It may be added that the numbers of observed points in the plots are generally not sufficient to establish very definitely the position of the maximum and minimum points on the curve with reference to the position of the counterweight in its revolution.

Fig. 13 gives the stresses in rail under the wheels for the high point and the low point of the curves of Fig. 12. The stresses for negative moment between wheels are also given; for some of the wheels no especially marked difference throughout the revolution was found and the mean of the observed stresses for negative bending moment is reported. Not enough difference was found under the front truck wheel throughout the revolution to warrant giving more than a straight-line average for the stress at this wheel. A similar condition was found under the trailer for a speed of 25 miles per hour, but at the

higher speed a noticeable variation exists, the high point of the curve occurring some time after the counterweights of the drivers have passed their high position.

In Table 5 are given the numerical values of the stress in rail under the several wheels as shown in Fig. 13. The mean values given are the mean values taken from the curves of Fig. 12 for an entire revolution.

In Table 6 are given ratios calculated from the data of Table 5. S_5 is the average stress in rail at 5 miles per hour. S_{25}, S_{40}, and S_{50} are the stresses in rail at the high point of curve for 25, 40, and 50 miles per hour, respectively. S_m is the stress found by taking the mean

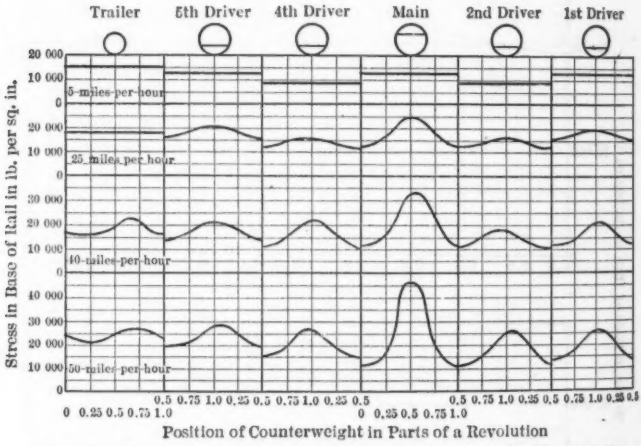

FIG. 12.—CURVES OF AVERAGE STRESS IN RAIL THROUGHOUT REVOLUTION OF DRIVER, SERIES 1, SANTA FÉ TYPE LOCOMOTIVE OF THE ST. LOUIS-SAN FRANCISCO RAILWAY.

ordinate of the curve for the speed used. $\frac{S_{50}}{S_5}$ (called total ratio), may be considered to represent the total effect of change in speed from 5 to 50 miles per hour, including the speed or impact effect and the effect of counterbalance. $\frac{S_m}{S_5}$ (the speed effect ratio) may be considered to represent the effect of speed as distinguished from effect of counterbalance. $\frac{S_{50} - S_m}{S_5}$ (the counterbalance effect) may be considered to represent the effect (increase or decrease) which may be attributed to counterbalance. The division into speed effect and counterbalance effect in this way is quite imperfect, but may be of service in helping to judge of these two effects.

Ratios for calculated effect of counterbalance in producing stress in rail are also given in Table 6. These were obtained by dividing the calculated resulting upward or downward pressure effect due to the dynamic augment of the rotating parts at the given speed by the static load pressure, the effect of all adjacent wheels upon moment and stress being considered in determining both static effect and counterbalance effect, as has already been referred to in Article 4, "The Problem of Counterbalancing the Locomotive". To make clearer the method of calculation used in determining the calculated counterbalance ratio, as affecting the moments and stresses in rail, the following examples may be cited.

A reference to the principles given in the analysis of track action in the first progress report (pages 1203 to 1215) will show that the moment and therefore the stress produced by a combination of wheel loads may be found by calculating the load for a single wheel which is equivalent to the combined effect of the several wheels in moment-producing effect, and using the resulting load (which will be termed the equivalent single wheel load) in the formula for bending moment in the rail. This formula for bending moment in the rail then is $M_0 = 0.318\ Px_1$ (Equation (8), page 1205 of the first progress report), where P is the equivalent single wheel load and x_1 is the distance from wheel load to point of zero bending moment in rail for a single wheel load on the track in question.

The calculation of the equivalent single wheel load may then be made by adding algebraically to the load on the wheel itself the effect of the

adjoining wheels, much as was done by means of ratios on page 1210 of the first progress report, since the combined effect is the algebraic sum of the effects of the individual wheel loads. Thus, for the Santa Fe type locomotive, the equivalent single wheel load for finding moments and stresses under the main driver for static loading by this method would be found as follows, using $x_1 = 29.3$ in., and taking values of coefficients corresponding to the effect at various distances found on the master diagram for bending moments given in Fig. 5, page 1207 of the first progress report:

Main driver load			+ 31 600
Effect of first driver	$\frac{x}{x_1} = 4.30$	29 500 × (— 0.03)	— 900
Effect of second driver	$\frac{x}{x_1} = 2.15$	28 100 × (— 0.21)	— 5 900
Effect of fourth driver	$\frac{x}{x_1} = 2.15$	29 600 × (— 0.21)	— 6 200
Effect of fifth driver	$\frac{x}{x_1} = 4.30$	29 200 × (— 0.03)	— 900
Equivalent single wheel load at position of main driver			+ 17 700

The equivalent additional single wheel load (positive or negative) due to counterbalance for a speed of 50 miles per hour, for use in calculating the additional stress in rail due to counterbalance, would be found as follows. For the counterbalance used in the calculations the upward and downward pressures at 50 miles per hour, the dynamic augments of the rotating parts, were calculated to be + 12 300, + 12 400, — 24 900, + 12 400, and + 12 300 lb. for the first, second, third, fourth, and fifth drivers, respectively. The equivalent additional single wheel load at the main driver, which may be attributed to the counterbalance will first be calculated for the counterweight up. For this position underbalance is counted as positive, since it produces additional downward pressure when the counterweight is up, and overbalance on the adjacent driver is counted as negative since it increases the pressure on that wheel and thus lightens the effect at the wheel under consideration. The values of the factors used are taken from Fig. 5 of the first progress report.

Dynamic augment of main driver		+ 24 900
Effect of dynamic augment of first driver	12 300 × 0.03	+ 400
Effect of dynamic augment of second driver	12 400 × 0.21	+ 2 600
Effect of dynamic augment of fourth driver	12 400 × 0.21	+ 2 600
Effect of dynamic augment of fifth driver	12 300 × 0.03	+ 400
Equivalent additional single wheel load at position of main driver		+ 30 900
Equivalent static wheel load		+ 17 700
Total equivalent single wheel load at 50 miles per hour		+ 48 600

Hence, the following ratio is obtained:

$$\frac{\text{Equivalent additional single wheel load at 50 m. p. h.}}{\text{Equivalent static single wheel load}} = \frac{30\,900}{17\,700} = 1.74$$

This ratio represents the moment-making effect of the counterbalance expressed in terms of the moment-making load under static conditions; it may be considered that the stress in rail will increase as this ratio if the assumptions involved in the analysis are not modified by other features.

For counterweight down the effects of the counterbalance for the wheels adjoining the main driver will each be negative instead of positive, and the total equivalent static wheel load is $-30\,900 + 17\,700 = -13\,200$. The ratio for the counterweight down then is $-\frac{30\,700}{17\,700} = -1.74$. The negative moment in rail here indicated should not be taken to mean that there is negative pressure or no pressure on the rail at the main driver, or that the rail is not depressed; the pressure of the main driver on the rail by the analysis used would be 6 700 lb. for the assumed condition. The rail depression would be that due to a single wheel load of 13 500 lb.

For the fourth driver the calculations for static load are:

Fourth driver load		+ 29 600
Effect of second driver $\frac{x}{x_1} = 4.30$	28 100 × (− 0.03)	− 800
Effect of main driver $\frac{x}{x_1} = 2.15$	31 600 × 0.21	− 6 600
Effect of fifth driver $\frac{x}{x_1} = 2.15$	29 200 × 0.21	− 6 100
Equivalent single wheel load at position of fourth driver		+ 16 100

The equivalent additional single wheel load at the fourth driver, which may be attributed to counterbalance, for counterweight up, is found as follows:

Dynamic augment of fourth driver		− 12 400
Effect of dynamic augment of second driver	− 12 400 × (− 0.03)	+ 400
Effect of dynamic augment of main driver	24 900 × (− 0.21)	− 5 200
Effect of dynamic augment of fifth driver	− 12 300 × (− 0.21)	+ 2 600
Equivalent additional single wheel load at position of fourth driver		− 14 600
Equivalent static wheel load		+ 16 100
Total equivalent single wheel load at 50 miles per hour		+ 1 500

The ratio of equivalent additional single wheel load at 50 miles per hour to equivalent static single wheel load (calculated counterbalance ratio) then is $-\frac{14\,600}{16\,100} = -0.91$.

For counterweight down the total equivalent single wheel load becomes + 30 700 and the counterbalance ratio + 0.91.

Values of the calculated effect of counterbalance, obtained by the method described, are given in Table 6 for all the drivers and the trailer and for three speeds. The values in effect give the ratio of the calculated stress in rail due to counterbalance to the stress in rail due to static loading.

The calculated stress in rail due to static loading and to counterbalance may be found, of course, by applying the equivalent single wheel load obtained as above in Equation (8) of the first progress report giving the bending moment in rail, $M_0 = 0.318\ P\ x_1$, and substituting the value of the section modulus of the rail used. Values so computed are given in the tables.

The data of the tests given in the diagrams and tables for the Santa Fe type locomotive show considerable variations in stress with changes in speed. For the position of counterweight which gives maximum effect (counterweight up for the main driver and counterweight down for the other drivers) there is a material increase in stress with increase in speed, particularly at the main driver where the stress at 50 miles per hour is 46 800 lb. per sq. in., a ratio of 3.75 to the stress found at 5 miles per hour. For the opposite position of counterweight the change in stress with increase in speed is generally small, with several cases of decrease in stress.

The ratios given in Table 6 permit some comparison to be made on the effect of speed and of counterbalance taken separately, though, as has been stated, the method of separation is somewhat crude. By this method of separation, the effect of speed alone at 50 miles per hour is to give an additional stress in rail above the stress at a speed of 5 miles per hour which varies from 53 to 98 per cent. The main driver shows the greatest increase due to speed. The increase in stress due to counterbalance for the position which gives maximum effect does not vary greatly from the ratios for calculated effect of counterbalance; for some drivers it is more and for others less. For the main driver the increase in stress at 50 miles per hour, due to speed alone, is 92% of the stress found at 5 miles per hour. For the opposite position of counterweight the stress is generally greater than that which would be expected from calculations of counterbalance effect. It is to be expected that the results will show irregularities and that variations will occur. The deflection of the locomotive springs and the depression of track will change in amount at each wheel with the changing pressure as the position of counterweight changes, and these changes will

influence the pressures in the rail. Such changes may be relatively large at the main driver and adjoining drivers since the lack of balance for adjoining drivers is in opposite directions. The effect of the equalizing levers in transferring load to adjoining wheels complicates the situation and may account for some variations in stress.

For a speed of 40 miles per hour, relations similar to those found at 50 miles per hour exist. The stress found under the main driver is 2.58 times that at a speed of 5 miles per hour and the counterbalance effect itself results in doubling the stress in rail. At 25 miles per hour, the combined effect of speed and counterbalance nearly doubles the stress under the main driver, 58% of this increase apparently being attributable to effect of counterbalance. The ratios for speed and for counterbalance effect at this speed are similar to those found for 50 miles per hour.

It may be noted that had the readings on the right side of the locomotive only been used in this comparison the stresses at the several speeds would have been lower and the ratios in Table 6 would have been higher. Considering the uncertainty concerning the weights of the rotating parts and especially that concerning their exact distribution among the several drivers, it cannot be expected that a closer comparison may be made. The effect of speed at 50 miles per hour is to give an increase in rail stresses, ranging from 50 to 100%, and the effect of counterbalance in producing increased stress is close to that obtained by the method of calculation used.

The calculation for effect of counterbalance at the main driver given on page 1444 indicates that when the counterweight is down, the combined effect of driver loads and counterbalance effect would produce a negative moment in the rail at the main driver, and this negative moment might be expected if the effect of speed did not itself contribute to a positive moment at the wheel. This effect of speed is so large that in all the tests the stress at the main driver with counterweight down indicates the presence always of a positive bending moment. The foregoing relates to stress and bending moment—the calculated rail pressure and rail depression have to be treated separately from stress and moment; even without the effect of speed there is no indication from the calculations given that the wheel would leave the rail.

Attention is called to the variation in stress at the trailer for the higher speeds. There is an appreciable change in stress as the counterweights of the drivers change position. The maximum stress occurs somewhat after the counterweight has reached its high position. Due to the large load on the trailer, its distance from other wheels, and the effect of counterbalance, the stress at this wheel is high, the highest of any except that at the main driver and except for the fifth driver at 5 miles per hour. The data of Series 2 will be found to give similar results. The time at which the maximum stress is found ranges from

the counterweight at six-tenths of a revolution after the counterweight is down to eight-tenths of a revolution; it occurs, therefore, between the positions of counterweight which give the minimum and the maximum stress at the driver ahead of the trailer.

It will be remembered that the values of stresses in rail considered in the foregoing discussion were taken from the curves of averages and that the band which enclosed the greater number of the observations extends 3 000 or 5 000 lb. per sq. in. above the curve and a similar distance below it. Above and below this band are other observed points, and the average of these outlying points is still 3 000 lb. per sq. in. above and below the limit of the bands. It may be expected that values may frequently be developed which are 3 000 or 5 000 lb. per sq. in. higher or lower than those used in the discussion and that not infrequently values of 3 000 lb. per sq. in. still greater or less will be found. Values 6 000 to 8 000 lb. per sq. in. greater than the stresses given in the discussion therefore may be expected not infrequently.

11.—The Santa Fe Type Locomotive; Rotating Parts Lightened.— In an effort to reduce the injurious effect of the Santa Fe type locomotives upon the track, the Railroad Company lightened certain of the rotating and reciprocating parts of Locomotive No. 19 by cutting away metal at various places. A series of runs were made with this locomotive (Series 2) and comparisons will be made with the results of Series 1 which have been described in the preceding article. In making a comparison it should be borne in mind that the results found with two locomotives of nominally the same construction may differ considerably. The tests of Series 1, with locomotives as received from the builders, were made with two locomotives, Nos. 22 and 28. The tests of Series 2 were made at the same place in the track, with the instruments distributed in the same way, and the conditions of the test were much the same. The readings from the instrument on the left rail were included in the data used, as was the case for Series 1.

The statement from the office of the General Superintendent of Motive Power shows reductions in weight of rotating parts as follows: back end of main rod (considered to be tributary to the main driver in calculating its dynamic augment), 42 lb.; front end of side rod (tributary to first driver), no change; front intermediate side rod (tributary to second driver), 20 lb.; middle connecting side rod (tributary to main driver), 75 lb.; back intermediate side rod (tributary to fourth driver), 20 lb.; back end side rod (tributary to fifth driver), no change. Eighty-six pounds of metal were taken from the piston; 52 lb. from the cross-head, and 34 lb. from the front end of the main rod, but whatever the effect of the lightening of these reciprocating parts on the locomotive itself and on the effect of speed upon the track, this reduction does not alter the effect of rotating parts.

In computing the effect of counterbalance for Locomotive No. 19, the weights of rotating parts given in Table 1, page 1423, were reduced by the amounts previously given. The equivalent counterbalance at the pin of the main driver is 629 lb. instead of 746 lb. and that of the second and fourth driver 390 lb. instead of 370 lb. It will be seen that the underbalance of the main driver is decreased and the overbalance (for rotating parts) of the other two drivers named is increased, the first and fifth drivers not having any change. The effect of the increase of overbalance of the second and fourth drivers upon the stress under these two drivers is nearly neutralized by the influence of the decrease in underbalance of the main driver, and calculations indicate that the resulting effect at the second and fourth drivers is negligible. The calculated effect at the main driver however will be to decrease the stress in rail due to dynamic augment about 11 per cent. The calculated decrease in stress in rail at the main driver for these conditions would be 1 800 lb. per sq. in. at 40 miles per hour and 2 800 lb. per sq. in. at 50 miles per hour.

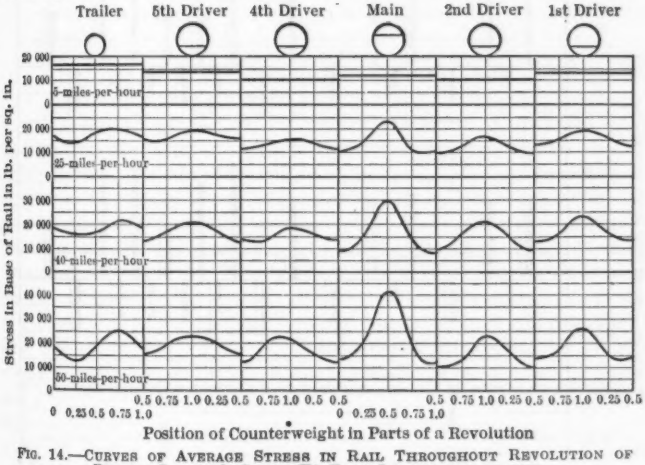

FIG. 14.—CURVES OF AVERAGE STRESS IN RAIL THROUGHOUT REVOLUTION OF DRIVER, SERIES 2, SANTA FÉ TYPE LOCOMOTIVE OF THE ST. LOUIS-SAN FRANCISCO RAILWAY.

Fig. 14 gives the stress in base of rail throughout a revolution of driver for all the drivers and the trailer for Series 2, obtained in the same way as were those already given for Series 1, and Fig. 15 gives the value of the stresses in base of rail at the various wheels for the high point and the low point of these stress curves. Table 7 gives numerical values of these stresses, as well as the values of the mean stress for the several stress curves. In Table 8 are given ratios which

may be considered to express the effect of speed and the effect of counterbalance. These correspond to the ratios given in Table 6. Ratios expressing the calculated relative effect of counterbalance are also given.

Comparisons of the two series to determine effect of counterbalance have less value because the locomotives used in the two series give somewhat different speed effects and different distributions of stress under the several drivers, the increase in mean stress over that at 5 miles per hour being generally smaller in Series 2 than in Series 1. The advantage obtained through lightening the rotating parts may be shown by comparing the stress at the main driver with the average of the stresses at the adjacent drivers, taking into account also the differences in stress which exist at 5 miles per hour for the two series, differences which may be due to a different distribution of load among the drivers in the locomotives. For both counterweight up and counterweight down the difference between the stress at the main driver and the average of the stresses at the adjacent drivers is substantially less for Locomotive No. 19 than for the other two locomotives; this is true at speeds of 40 and 50 miles per hour to an amount beyond the difference in stress at these drivers for 5 miles per hour.

The effect of the lightening of rotating parts is seen also by comparing the differences between maximum stress and mean stress for the main driver and adjoining drivers for Series 1 and 2 (Tables 5 and 7); the effect of counterbalance is less for the main driver in Series 2 than in Series 1 as compared with the change for the average of the two adja-

cent drivers. It seems probable that the lower average increase in stress due to speed in Series 2 may also be due, in part, to the lightening of parts.

A marked difference in the two series, however, lies in the greater effect of speed and counterbalance for 50 miles per hour found in Series 1 as compared with Series 2. Much of this difference is in speed effect alone. If the stresses at drivers and trailer be summed for the two series it will be seen that for 50 miles per hour the sums of maximum stress, minimum stress, mean stress, stress with counterweight up, and stress with counterweight down will each be about 10% of the mean stress more for Series 1 than for Series 2, while for 25 and 40 miles per hour there is relatively little difference. The same effect may be seen by comparing the ratios of Tables 6 and 8.

As has already been stated, in Series 1, Locomotive No. 22 was used in the runs at 5 and 40 miles per hour and part of the runs at 25 miles per hour, and Locomotive No. 28 was used in the remaining runs at 25 miles per hour and in all the runs at 50 miles per hour. The results for the tests at 25 miles per hour have not been separated for the two locomotives used in Series 1. The results show that locomotives of the same nominal construction may have quite different distribution of loads among the drivers.

The stresses in rail for the locomotive with rotating parts lightened are still very high at speeds of 25 miles per hour or more.

12.—Comparison of Stress Under the Two Sides of the Santa Fe Type Locomotive.—The experience of the St. Louis-San Francisco Railway with these Santa Fe type locomotives gave some indication that injuries were more common or greater in the rail at the left side of the locomotive than in the other rail. To learn whether the stresses in rail were the same under the two sides of the locomotive, tests were made with Locomotive No. 22. The four instruments were placed on one rail as shown in Fig. 4, and runs were made in one direction at speeds of 5, 25, and 40 miles per hour, forming Series 3, the instruments being on the rail at right side of locomotive. The locomotive was then reversed in direction and runs over the same track were made in this direction at the same speeds, forming Series 4 for instruments on rail at left side of locomotive. The instruments retaining their position on the same rail and other conditions remaining the same, and all the tests being made on one day, results were thus obtained for the effect of the two sides of the locomotive which seem comparable.

The data were reduced in the usual way and plotted according to position of counterweight, and the maximum value of the stress curve for each wheel at each speed was determined. It was found that the stress in rail under the left side of this locomotive was considerably greater than that under the right side. That this difference is not

caused by speed or counterbalance is indicated by a marked difference at a speed of 5 miles per hour; the sum of the stresses in rail at the five drivers, trailer, and truck wheel, as found for the left side of the locomotive, is as much as 20% greater than the sum of the corresponding stresses for the right side of the locomotive. A similar difference is found at all speeds, both for mean stresses and for maximum stresses. It seems that the difference is due to a cause not related to speed.

That this excess of stress at one side of the locomotive was not due to methods of testing is shown by the stresses at the wheels under the tender. The average stress for the three speeds for Series 3 (rail at right side of locomotive) is 15 500 lb. per sq. in. and for Series 4 (rail at left side of locomotive) is 15 300 lb. per sq. in. A few runs of Series 3 were made before the noon hour; the remaining runs and all of Series 4 were made after the noon hour. There would be some decrease in the load of coal and water, but this would not be large.

In all the other tests with the Santa Fe type locomotive, one instrument was placed on the rail at the left side of the locomotive opposite the middle one of the three instruments on the rail at the right side, as shown in Fig. 4. In the plots of data, it was found that the results obtained with the instrument at the left side generally average higher than the results obtained with the other instruments, thus agreeing in this respect with the series just discussed. Whatever the cause of this variation, it has made complications in the interpretation of the data for other purposes and has thrown uncertainty on some comparisons which it was desired to make, but the relatively small amount of data available has made it seem best generally to include all the instrumental results even with this added complication. The use of one instrument on the second rail has seemed advisable for the purpose of checking up in possible cases of irregular or unexpected values in the data.

The reason for this difference in stress developed on the two sides of the locomotive is not known; it is planned to make a further investigation of the conditions.

It should be noted that the lateral bending of rail due to nosing is not here discussed; it may have an important relation to rail injury.

13.—The Effect of Santa Fe Type Locomotive Upon Rail and Track.—The tests made with the locomotive of the Santa Fe type gave an interesting opportunity to find the effect upon rail stresses produced when the desired amount of counterweight is not or can not be placed on the main driver, but instead the deficiency for the given wheel is distributed among the other drivers which thereby have their counterweight increased above what is already an overbalance so far as rotating parts and vertical pressure are concerned. The increased stress in the rail is due not alone to the increased pressure on the rail given by the excess of weight of rotating parts on the main driver when the crank pin is

down, but it may be seen from the illustrative calculations given in Article 10 on "Effect of Speed and Counterbalance" that the overbalance in the adjacent drivers at the same time relieves part of the pressure on the rail at those drivers and the effect of this decrease in pressure is to increase the bending moment in the rail under the main driver.

Similarly, the addition of counterweight to drivers other than the main driver not only increases the counterweight effect in the rail at these drivers (which are already overbalanced so far as rotating parts are concerned), but the deficiency in the counterweight of the main driver decreases the pressure on the rail at the main driver when the counterweight is down and thus increases the moment in the rail at the adjacent drivers. The existence of these influences is evident from the analysis and illustrations already given. Whatever may be the effect of this abnormal distribution of counterweight upon the frame of the locomotive or upon its riding qualities, it is evident that a deviation from a uniformity of counterbalance effect among the several drivers aggravates conditions producing stresses in rail which otherwise may be bad enough.

The Santa Fe type locomotives used in the tests may seem extreme in the amount and distribution of counterweight, but the underbalance of the main driver in locomotives of this type as used on some railroads is reported to be considerably greater than that found on these locomotives; on the other hand, the Santa Fe type locomotive of at least one railroad has an underbalance of less than half that of those on the St. Louis-San Francisco Railway. In other features of the design also these locomotives were not calculated to produce low or even stresses in the rail. The weight given for the main driver, 31 600 lb., is considerably greater than that on the second and fourth drivers, which might advantageously be given more load than the first and fifth. Even at low speeds the second and fourth drivers give considerably lower stresses than the others. Besides, the effect of the cylinder pressure at mid-stroke when the locomotive is working is to give a vertical component at the crank pin which serves to increase the pressure on the rail under the main driver both for counterweight up and counterweight down. The weight on the trailer, a wheel located some distance from other wheels, and thus having little moment-decreasing influence from the other wheels in these locomotives, is too great to produce even effects in rail stresses, the stress in rail at this wheel at low speeds (see Table 5) being considerably greater than those at the drivers, and at higher speeds generally being the highest at any point except at the main driver.

The stresses in rail produced by these locomotives at speeds of 25 miles per hour are high. It should be borne in mind, too, that the values under discussion are the average stresses for the runs, and that the occa-

sional maximum stress is much higher, and that the stress at one side of the rail will be still higher. Speed and counterbalance were found to increase stresses very rapidly. For the main driver the ratios of the stresses at the higher speeds to the stress at 5 miles per hour (2.04 for 25 miles per hour, 2.54 for 40 miles per hour, and 3.68 for 50 miles per hour) show undesirable and unsatisfactory conditions in a locomotive in so far as the effect on the maintenance and life of the track is concerned. The occurrence of stresses in base of rail (the average of the values at the two edges) as high as 52 000 lb. per sq. in. (and 10% higher in head of rail), observed at high speeds in a number of cases where the records were well defined, shows that it is not strange that kinks and rail failures were produced in the regular service of these locomotives. In some of the runs at 50 miles per hour, kinks in rail were developed near the rail on which instruments were placed. Even at lower speeds than those which may have produced such visible injury to track, the punishment of the track and the effect of continued application of such stresses probably would be sufficient to cause considerable injury to the track structure. Such locomotives should run only at low speeds, and every precaution should be taken to prevent even the occasional use of higher speeds on heavy down grades in undulating country or through other carelessness. The observance of much higher stresses under the left side of the locomotive than under the right it is hoped will lead to investigation to determine the origin of this undesirable effect upon track.

14.—Tests with the Pacific Type Locomotive.—The main purpose of the tests with the Pacific type of passenger locomotive made on the St. Louis-San Francisco Railway was to find the increase in stress in rail due to speed and counterbalance. The Railroad Company, however, desired to learn the effect of certain variations in these locomotives—the addition of a mechanical stoker, different arrangements of an equalizing lever, and the lightening of rotating parts—and the tests were outlined with a view of including the effect of these variations in the locomotives. Part of the changes in locomotive were relatively small and their extent had not been realized when the tests were started; the resulting change in distribution of load among the several wheels was also uncertain. The demands for locomotives under the existing traffic conditions and the beginning of winter weather made it impracticable to extend the tests to secure an adequate number of runs for some of the purposes of the test. In getting the effect of speed and counterbalance, it has been found best to group series of tests which have different locomotives and different conditions of locomotive, so that some of the effects may be masked by the differing conditions

and the real increases due to speed and counterbalance therefore may be greater than the values reported indicate.

Table 4 gives the variations in the Pacific type locomotives used. Series 8 to 12 were made with the locomotives as received from the builders except as the position of the pin in the equalizing lever was changed for some of the tests. The second location of test (rail adjoining that used for the first test) was used to determine whether the first test location was in any way abnormal; a comparison of the results indicate that there was little difference in conditions.

Series 5 and 6 made with Locomotive No. 1061 having a mechanical stoker added were made at the beginning of the test work on the St. Louis-San Francisco Railway. It is evident from the data that the instruments were not working satisfactorily or the observers were not in good practice. Many records were so indefinite as not to be usable. As the number of runs was small, the number of definite values obtained was too small to use in making comparisons, and these two series will not be reported. As the stoker weighed only 3 500 lb. and the weight added to one wheel was probably much less than 1 000 lb., a large number of runs would have been necessary to secure an adequate amount of data for making a proper comparison.

The Pacific type locomotives were received and generally used with the pin in the rear hole of the equalizer bar at the rear of the locomotive. The change of the pin to the middle hole releases weight from the trailer and increases the weight on the drivers. It is also expected to decrease the weight on the front trucks. The changes in the weights on the several wheels as calculated by the Mechanical Department of the railway may be seen from the following weights:

	Trailer.	Third driver.	Main driver.	First driver.	Two truck wheels.
Pin in rear hole	32 150	29 700	32 250	29 750	28 850
Pin in middle hole..	28 850	31 950	34 450	31 950	25 550

These calculated values indicate that by the change in length of equalizing bars, 3 300 lb. is released from the trailer and 3 300 lb. from the two truck wheels and that this 6 600 lb. is divided equally among the three drivers. Based on the calculated or assumed distribution of the weight of the locomotive among the several wheels, the stress in the rail calculated by the method of combination of wheel loads given in the first progress report would be decreased by 2 300 lb. per sq. in. under the trailer and 1 000 and 1 400 lb. per sq. in., respectively, under the two truck wheels, while the stresses under the three drivers would be increased by 1 800, 1 000, and 1 500 lb. per sq. in., respectively. The test results are not fully comparable for this purpose, and the results of the series with the pin in the two positions are not entirely concordant. The average of the results of the several series indicates that changing

the pin to the middle hole decreases the stress in rail under the trailer, and increases the stress under the three drivers, with little change under the truck wheels. The amount of this change, however, as given by the averages of Series 7 to 12, is much less than the change found by calculation on the basis of the assumed distributions of weight. The effect of speed was noticeably less at the trailer with the pin in the middle hole.

Series 9, 10, 11, and 12 may be grouped together for finding the effect of speed and counterbalance, though the differences in conditions for the four series make comparisons in some ways somewhat uncertain. As there were about the same number of observations for each position of pin in the equalizing bar, this variation should not affect the results materially. The effect of differences in locomotives and of differences in track in the two locations of course is not known, but it is thought to be not large.

The observed values of stresses in base of rail for each speed in each series were plotted with respect to position of counterweight, the values of the plotted points in groups for each twentieth of a revolution were then averaged and a curve drawn to represent as well as possible the position and trend of these points, as has already been described for the tests with the Santa Fe type locomotive. The data for each speed of the four series (9, 10, 11, and 12) were also plotted together and curves drawn which represent the averages of the four series. Fig. 16 gives the resulting curves for the combined series. The maximum, minimum, and mean values for the curves were taken from the diagrams. The values of the stress in rail for the four series and the combined series are given in Table 9. It should be noted that, as was the case in the tests with the Santa Fe type locomotive, the greater number of the plotted observed values was found in a belt on each side of the curve of averages in the diagrams of data, the limits of the belt being 3 000 to 5 000 lb. per sq. in. above and below the curves, while still other points were above and below the belt. Fig. 17 shows graphically the principal stresses of the combined four series, including the average negative stress at points between wheels.

In Table 10 are given the ratios calculated from the data of Table 9 for the combined four series. S_5, S_{45}, and S_{60} are the stresses in rail at speeds of 5, 45, and 60 miles per hour, respectively. S_m is the mean value of the stress curve for the speed used. The total ratio, speed effect ratio, and counterbalance ratio are used as in the discussion of the counterweight with the Santa Fe type locomotive. Calculated counterbalance ratios, obtained with the data of counterbalance given in Article 5 on "The Locomotives", by the method already used, are also given in Table 10. The calculated upward and downward pressures at 60 miles per hour are 12 800, 10 000, and 13 000 lb. for the first, second, and third drivers, respectively. The downward and upward pressures

TABLE 9.—Stresses in Rail with Pacific Type Locomotive of the St. Louis-San Francisco Railway. Maximum, Minimum, and Mean Values from Curves for Series 9, 10, 11, and 12.

were considered as positive and negative loads at the several drivers, and the additional equivalent single wheel load for this combination of added loads was calculated for each wheel by the method described in the case of the Santa Fe type locomotive. The ratios of the resulting values to the equivalent single wheel loads found for the combination of nominal static wheel loads was calculated, and is given as the calculated counterbalance ratio.

The ratios in Table 10 may be considered to separate the effect of counterbalance and the effect of speed alone, though it must not be expected that the division of effect will be accurate.

It is seen that the maximum stress in rail at the first and third driver occurs when the counterweight is down at speeds of both 45 and 60 miles per hour, while the maximum stress at the main driver

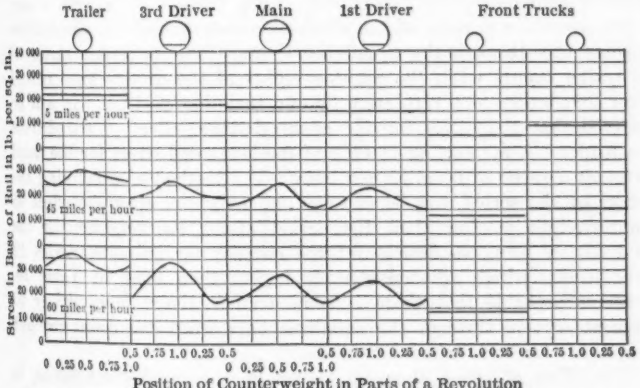

FIG. 16.—CURVES OF AVERAGE STRESS IN RAIL THROUGHOUT REVOLUTION OF DRIVER, SERIES 9, 10, 11, AND 12 COMBINED, PACIFIC TYPE LOCOMOTIVE OF THE ST. LOUIS-SAN FRANCISCO RAILWAY.

occurs when the counterweight is up. The maximum stress at the trailer occurs when the counterweight of the drivers is up, the exact position being when the drivers have turned about four-tenths of a revolution from the down position of the counterweight. The signs of the counterbalance ratio for the main driver given in Table 10, it is seen, are opposite to the signs of the observed counterbalance ratio for the main driver, while for the other wheels the signs of the calculated and the observed ratios agree.

No explanation is offered except that the weights of the rotating parts may be different from those given in Table 2, or that the assumed effect of such parts as the main rod is in error. The effect of the main rod and side rod being outside the plane of the driver seems to account for only part of the discrepancy. The results are so pronounced and

the information on the position of counterweight for the observations so definite and so general that no doubt can be thrown on the character of the test data in this respect. It may be added that it would not require a large discrepancy in the amount and position of the counterweight of the main driver, or in the weight of the rotating parts tributary to this driver, to produce quite a change in the calculated vertical pressure at the down position of the counterweight, taking into account the effect of the dynamic augment of the adjacent drivers upon the vertical pressure at the main driver. Possibly the weight of rotating parts given may not have been properly divided among the three drivers.

It will be noted that the counterbalance effect upon the trailer is considerably larger than would be expected from the effect due to relief of load on rail at third driver when the counterweight is up; it may receive a portion of the effect of counterbalance of the drivers in some way through the equalizing levers. The maximum stress at the trailer occurs when the counterweights of the drivers have moved about four-tenths of a revolution beyond their low position. It will be observed that the ratios for the counterbalance effect of the drivers is considerable, amounting to 44% of the low speed stress for the third driver at a speed of 60 miles per hour. The method of combining the results of the series may be expected to make the apparent effect of counterweight smaller than the actual effect, the tendency of the combination being to flatten out the curves; for example, Series 12 gives results which are considerably higher than those of Table 10. It seems probable that there is some transfer from main driver to adjacent drivers through the equalizer bars when the counterweight is up and *vice versa* when it is down.

The effect of speed alone, as shown by the speed effect ratios, is quite uniform for the drivers and trailer and is closely proportional to the speed. The additional stress due to speed alone is quite moderate for all three wheels. The stress at the truck wheels increases rapidly, though the value at 60 miles per hour is not excessive. Fig. 17 gives the stresses at the wheels of the tender for Series 9, 10, 11, and 12 combined. The effect of speed is considerable, the average ratio of stress at 45 and 60 miles per hour to the stress at 5 miles per hour being 1.95 and 2.25, respectively.

The total effect ratio indicates that the effect of speed and counterbalance together does not differ much for the several drivers and the trailer, either for maximum values or generally for minimum values. Attention is called to the very high stress at the trailer at all speeds and to the considerable increase with speed—this too in results which average the data with the equalizer pin in the two positions. The stress in the third driver was also high. It should be borne in mind, of course, that the band of the plotted data gave frequent points 4 000 lb.

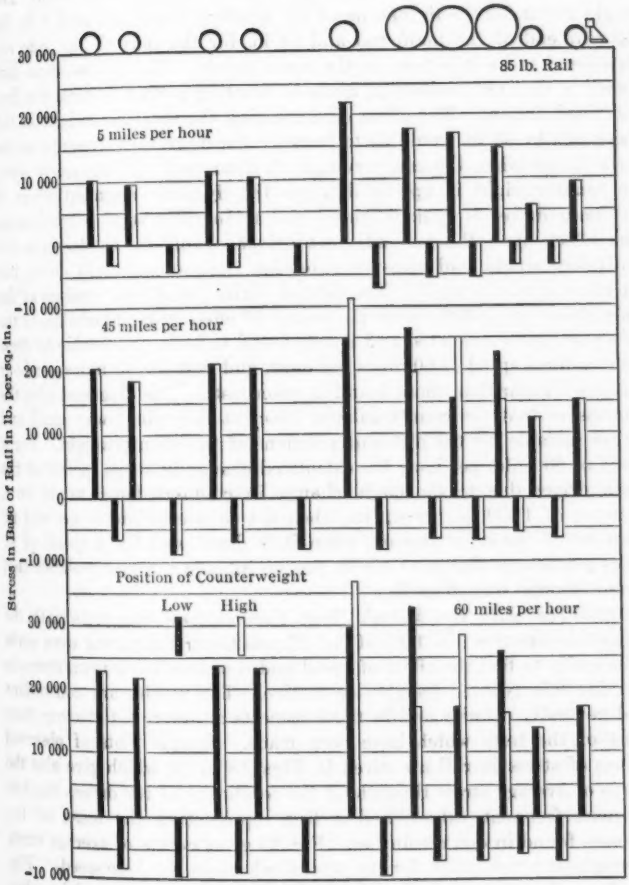

FIG. 17.—STRESS IN RAIL AT HIGH AND LOW POSITION OF COUNTERWEIGHT, SERIES 9, 10, 11, AND 12 COMBINED, PACIFIC TYPE LOCOMOTIVE OF THE ST. LOUIS-SAN FRANCISCO RAILWAY.

per sq. in. higher than these values and that occasional values were found which are more than 10 000 lb. per sq. in. higher.

The Railroad Company lightened somewhat some of the rotating and reciprocating parts of Locomotive No. 1063 by cutting away metal. The weight given for the lightening of the rotating parts included 9 lb. for the rear end of the main rod and 54 lb. for the part of the side rod considered to be tributary to the main driver. The information furnished is that no change was made in rotating parts affecting the first and third drivers. The effect of decreasing the rotating weight at the crank pin by 63 lb. would be to increase the downward pressure at the main driver when the counterweight is down and to decrease it when the counterweight is up—to decrease the dynamic augment effect if the main driver is underbalanced and to increase it if overbalanced. The effect upon the two adjacent drivers would be to decrease the equivalent single load pressure somewhat for counterweight down, but the effect would be small. The data of Series 7 and 8 for stresses at the main driver are indefinite on the matter of effect of counterbalance; the points are quite scattered and it was found to be impracticable to draw a curve for a speed of 60 miles per hour, and that for 45 miles per hour was less regular than those found in other tests. The diagrams give the impression that the counterbalance effect at this wheel was small and rather variable for the different positions of the counterweight. For a speed of 60 miles per hour the calculated change in stress in rail at the main driver due to the 63-lb. change in counterbalance would be a decrease of 1 500 lb. per sq. in. when the counterweight is up and an increase of the same amount when it is down, and for a speed of 45 miles per hour a change of 900 lb. per sq. in., and it seems probable that such a change was effected.

15.—Test with the Mikado Type Locomotive.—The tests with the Mikado locomotive No. 1769 of the Illinois Central Railroad were made principally to find the effect of speed and counterbalance upon stress in rail for this type of freight locomotive. The results are concordant and generally definite and in these respects are more satisfactory than most of the tests which have been made. Sample plots of observed values of stress in rail are given in Figs. 18 to 22, which give also the curve of average stress throughout the revolution of the driver, the belt of most frequent values, and a line representing the mean of the stresses found in one revolution. Fig. 23 gives curves of average stress throughout a revolution for the several wheels at the four speeds. Fig. 24 shows the stress at high point and low point of counterweight taken from these curves. These values of stress in rail are given in Table 11, together with the mean value for the curve of average stress.

Table 12 gives the total ratio (combined speed and counterbalance effect), speed effect ratio, $\frac{S_m}{S_5}$, and counterbalance effect ratio, the

nomenclature being the same as was used in the discussion of the tests with the Santa Fe and Pacific locomotives and the stress at 5 miles per hour being the divisor used in obtaining the ratios.

It will be noted that the stress at the first, second, and fourth drivers is greatest when the counterweight is down, and that the stress at the main driver is greatest when the counterweight is up. The stress at the trailer is greatest when the counterweights of the drivers are somewhat past their high position. The truck wheel shows the effect of counterbalance, the high stress in rail occurring when the counterweights of the drivers are slightly past the high position (about one-seventh of a revolution), and the corresponding low stress at the opposite position. The results indicate that the main driver is underbalanced for rotating parts, and that the other drivers are overbalanced.

The figures for counterbalance weights given by the Motive Power Department of the Illinois Central Railroad (see Table 3, page 1425), indicate the same condition of counterbalance for each driver, 263 lb. overbalance for rotating parts (to balance 60% of the reciprocating parts, considered to be taken by the four drivers equally). Not only is the position of counterweight of the main driver which gives the highest stress in rail the opposite of that obtained by analysis for the weights given in the table, but the counterbalance effect found for the several drivers is much larger than the calculated values. For the first, second,

and fourth drivers and for the speeds of 25, 35, and 45 miles per hour the average of the ratios expressing effect of counterbalance given in Table 12 is more than twice the calculated value. For the main driver at these three speeds the ratios expressing the counterbalance effect (0.33 at 25 miles per hour, 0.50 at 35 miles per hour, and 0.67 at 45 miles per hour) are three to four times the calculated values, and the high stresses occur when the counterweight is up instead of when it is down as would be expected from the counterbalance data given. A consideration of the planes in which the several rotating parts act only partly explains the discrepancy in the case of the main driver.

No explanation is offered for the remaining discrepancies. Possibly the weights of parts may not be correctly reported, and their distribu-

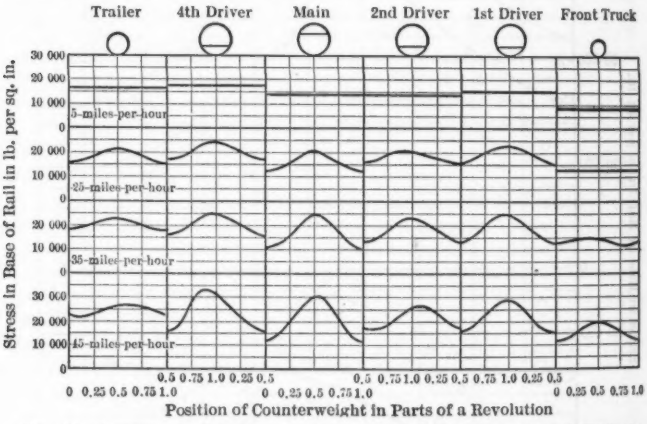

FIG. 23.—CURVES OF AVERAGE STRESS IN RAIL THROUGHOUT REVOLUTION OF DRIVER, MIKADO TYPE LOCOMOTIVE OF THE ILLINOIS CENTRAL RAILROAD.

tion may also not be correct. Although the counterbalance effects are generally not large, the additional stress at the main driver at 35 miles per hour (the speed limit given by the railway regulations) is 50% as great as the stress at 5 miles per hour, and the stresses due to counterbalancing would be materially less if the counterbalance effects were in the same direction for each driver.

The effect of speed alone, as shown by the speed ratios in Table 12, is about the same for the several drivers. The ratios for truck wheel and for trailer are considerably higher at the higher speeds.

16.—Relation of the Stresses at the Two Sides of the Base of Rail.— In the first progress report it was shown that lateral bending of the rail occurred to a considerable extent; that most frequently the rail was bent outwardly at a point under a wheel and inwardly at a point between

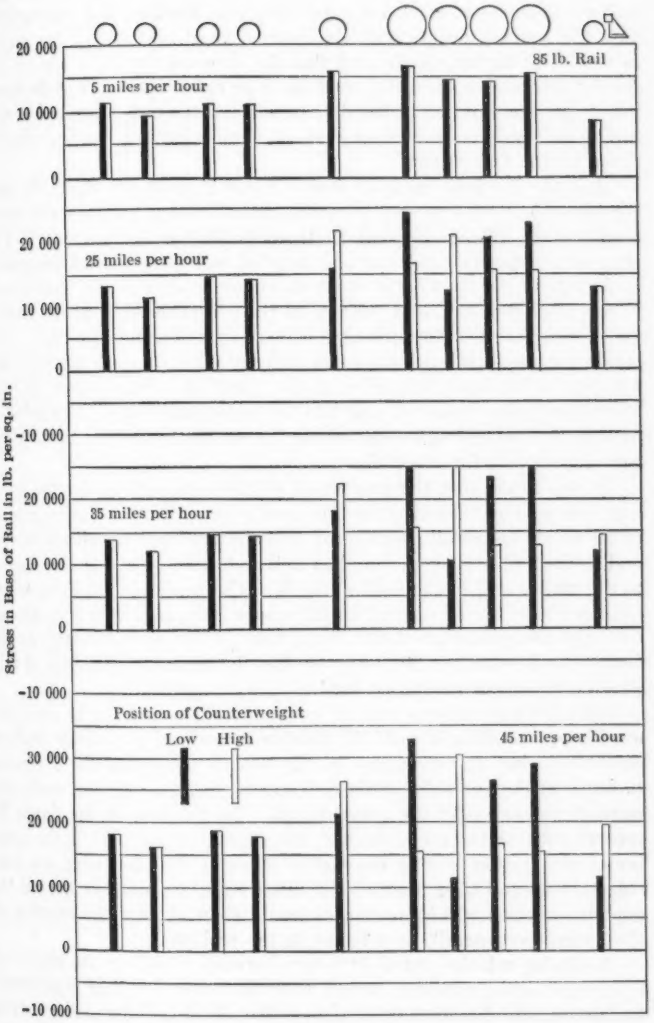

FIG. 24.—STRESS IN RAIL AT HIGH AND LOW POSITION OF COUNTERWEIGHT, MIKADO TYPE LOCOMOTIVE OF THE ILLINOIS CENTRAL RAILROAD.

wheels, though a flexure opposite to this also was frequent; that the change in gauge of track accompanying this bending was measurable; that the bending occurs with the locomotive at rest and at low speeds as well as at higher speeds; and that the stress at the outer edge of the base of rail may occasionally reach three or more times that at the inner edge. An examination of the data of some of the tests described in this report has been made with a view of supplementing the information given in the first report.

A study has been made of Series 1 and 2 (with the Santa Fe type locomotive), Series 10 and 12 (with the Pacific type), and the series made on the Illinois Central Railroad (with the Mikado type). The stresses for the two sides of the base of rail were plotted separately according to the position of the counterweight, and curves were drawn to represent the trend and position of the points throughout the revolution for stress at both outer edge of base of rail and inner edge. The curves for stress at outer edge and at inner edge are quite similar, that for outer edge being higher than the curve of average stress in base of rail heretofore reported, and that for inner edge lower. The point of maximum stress for outer edge generally comes a little later in the revolution than that for inner edge.

It was found that the average of all the observations for the outer edge was greater than that for the inner edge. This conclusion applies at all speeds and at all positions of the counterweight for all the drivers and to the higher stresses found as well as to the lower. It also applies to the trailer and to the tender wheels. The average of the stresses at the outer edge for the several wheels ranges from, say, 20 to 50% greater than the average at the inner edge; that is, the average stress at the outer edge is from 9 to 20% greater than the mean stress in base of rail, which is the stress heretofore used.

This indicates that a general condition exists tending to give outward lateral bending in rail. No further investigation has been made to determine what that condition is. It may be noted that the difference in stress at the two sides of the rail was as great, or greater, under the main driver as under the other drivers. In the case of the Santa Fe type this driver has no flange and was slightly worn. While the number of observations giving the higher stress at the outer edge was considerably greater than that at the inner edge, the number having the opposite relation was by no means small, showing that the swaying of the locomotive laterally is a factor in the problem.

A similar relation exists at points between wheels in the region of negative bending moment, though here the lateral bending is generally in the opposite direction from that at the wheel and the average stress at the inner edge is greater than that at the outer edge.

More important than the average value at the edges of the base of rail are the relative values of the individual observations. The ratios of

the stress at edge to the mean stress in base of rail were plotted. A study of these shows that in 15 to 20% of the observations, the stress at the outer edge is 33% or more greater than the mean stress in base of rail, in a few cases reaching an excess of 50% or more, and that this holds good throughout the revolution of the driver. An excess of 20% is quite common. A stress at inner edge 33% greater than the mean stress was found in, say, 5 to 8% of the observations. As an example of a large difference in stresses at the two edges, though not of a high ratio of stresses, values for the main driver of the Santa Fe type at a speed of 50 miles per hour may be cited, 36 400 lb. per sq. in. at the inner edge, and 55 000 lb. per sq. in. at the outer.

The lateral bending in rail has some bearing on the design of rail section and on the design of tie-plates. It will be seen that for the rail sections used, a ratio of stress at outer edge to mean stress in base of rail having a value of 1.33 means that the lateral bending moment in the rail is about 8% of the vertical bending moment required to develop the mean stress. It should be noted that the results herein presented were obtained with track which may be said to be in ordinarily good condition; the results given in the first progress report for track in poorer condition and for track with decayed ties show that the amount of lateral bending may be materially greater and that therefore the condition of the track is an important element in the problem.

17.—*General Discussion.*—In Figs. 25, 26, 27, and 28 the ratios for total effect, speed effect and counterbalance effect given in Tables 6, 8, 10, and 12 have been plotted. These ratios show the relation between the stress in rail at the several higher speeds and the stress in rail existing at a speed of 5 miles per hour. In all the series the total effect ratios are concordant and show a marked increase of stress with speed, the increase being faster than the first power of the speeds. The method used in making a division of this total effect ratio into effect of speed alone and effect of counterbalance is of course not accurate, and it may be expected that a large counterbalance effect will result in an increased speed effect as well. Fig. 29 gives the ratios for the average speed effect for the tender wheels of the three types of locomotives used, as well as the values of the average stresses at these wheels.

It will be noted that the increase in stress in rail at drivers and trailer beyond 5 miles per hour due to speed alone, varies almost directly as the increase in speed, though in a few instances it is at a somewhat faster rate. Averaging the values of the ratios at the drivers and trailer and for comparison using a speed of 50 miles per hour in all cases, it is seen that for this speed the increase in stress in rail due to speed alone over that at 5 miles per hour will be about 70% for Series 1 and 50% for Series 2 (average of 60% for the Santa Fe type locomotive used), about 35% for the Pacific type locomotives, and about 50% for the

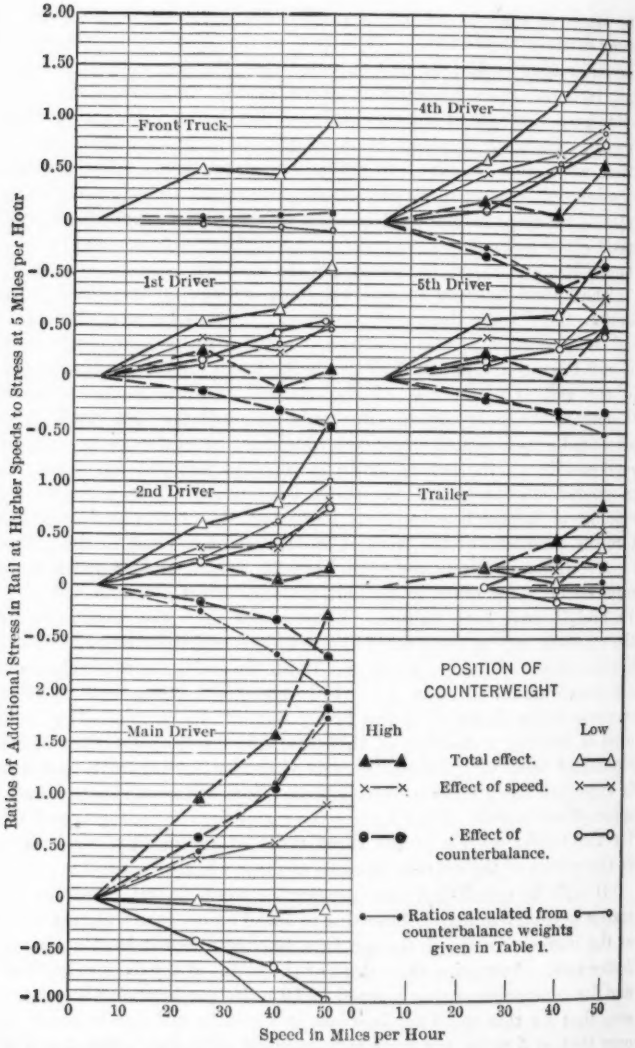

FIG. 25.—RATIOS OF TOTAL EFFECT, SPEED EFFECT, AND COUNTERBALANCE EFFECT TO STRESS AT 5 MILES PER HOUR, SERIES 1, SANTA FÉ TYPE LOCOMOTIVE OF THE ST. LOUIS-SAN FRANCISCO RAILWAY.

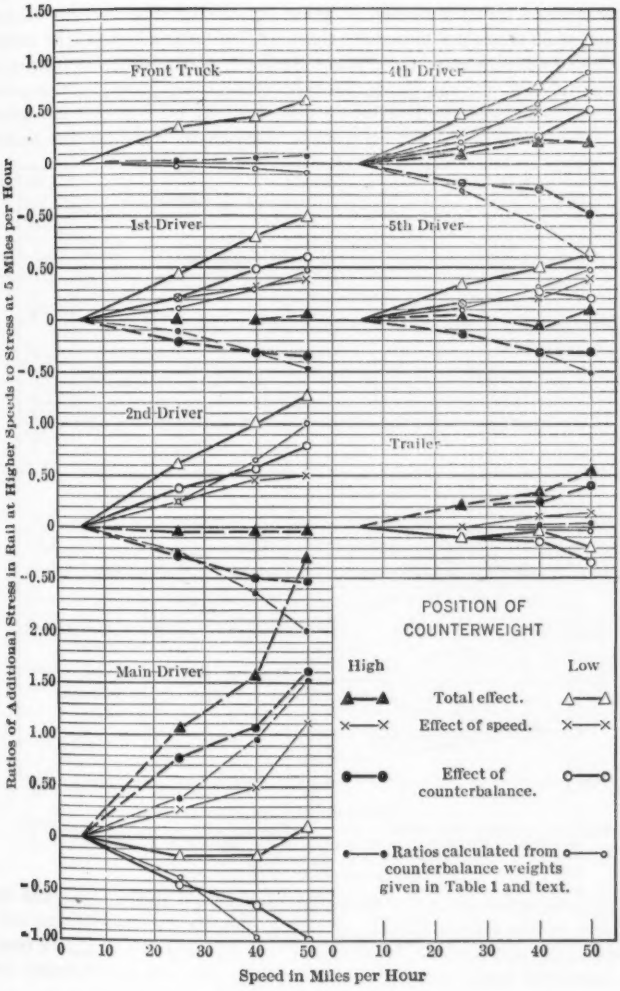

FIG. 26.—RATIOS OF TOTAL EFFECT, SPEED EFFECT, AND COUNTERBALANCE TO STRESS AT 5 MILES PER HOUR, SERIES 2, SANTA FÉ TYPE LOCOMOTIVE OF THE ST. LOUIS-SAN FRANCISCO RAILWAY.

Mikado type locomotive. At the tender wheels, the stresses in rail increase almost directly as the increase in speed. The increase in the stresses at 50 miles per hour over those at 5 miles per hour at the tender wheels is approximately as follows: Series 1, 50%, Series 2, 100% (an average of 75% for the Santa Fe type locomotive); Pacific locomotive 100%; and Mikado locomotive, 75 per cent. It is seen that the ratios found for the drivers are in general less than those for the tender

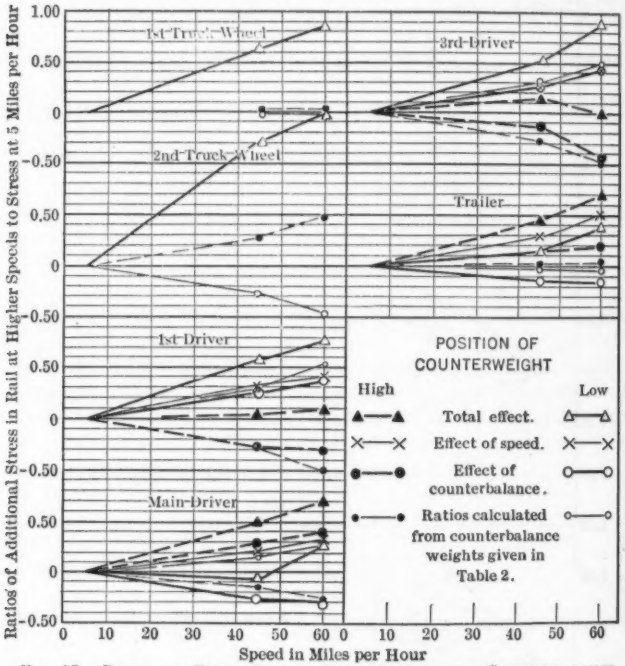

FIG. 27.—RATIOS OF TOTAL EFFECT, SPEED EFFECT, AND COUNTERBALANCE EFFECT TO STRESS AT 5 MILES PER HOUR, SERIES 9, 10, 11, AND 12 COMBINED, PACIFIC TYPE LOCOMOTIVE OF THE ST. LOUIS-SAN FRANCISCO RAILWAY.

wheels (the ratios do not include the effect of counterbalance), and the increase at the tender wheels varies considerably for the different locomotives. In some of the locomotives (particularly the Santa Fe type) the increased stress at some of the wheels is materially higher than the average values quoted above.

The counterbalance effect at low and high position of counterweight, with both underbalance and overbalance, is brought out in Figs. 25, 26, 27, and 28. It appears that with the main driver underbalanced

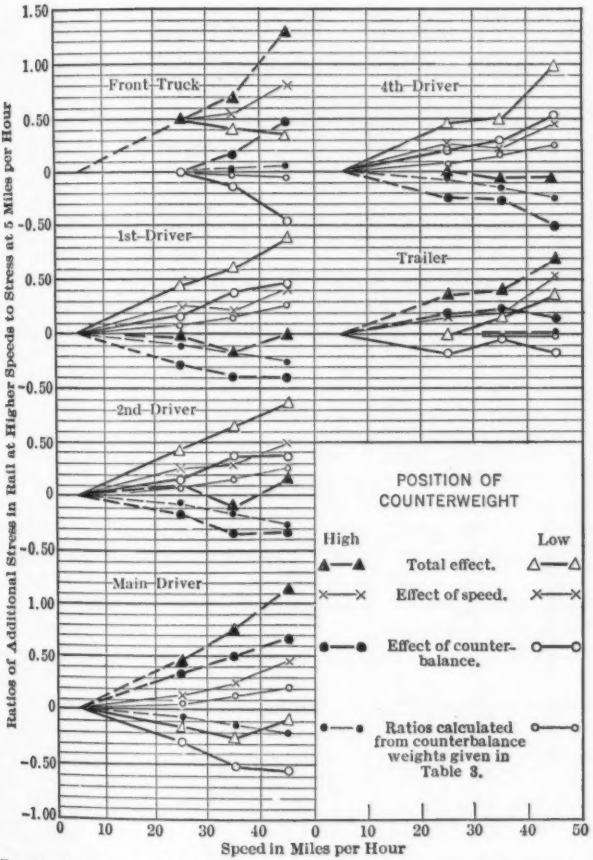

FIG. 28.—RATIOS OF TOTAL EFFECT, SPEED EFFECT, AND COUNTERBALANCE EFFECT TO STRESS AT 5 MILES PER HOUR, MIKADO TYPE LOCOMOTIVE OF THE ILLINOIS CENTRAL RAILROAD.

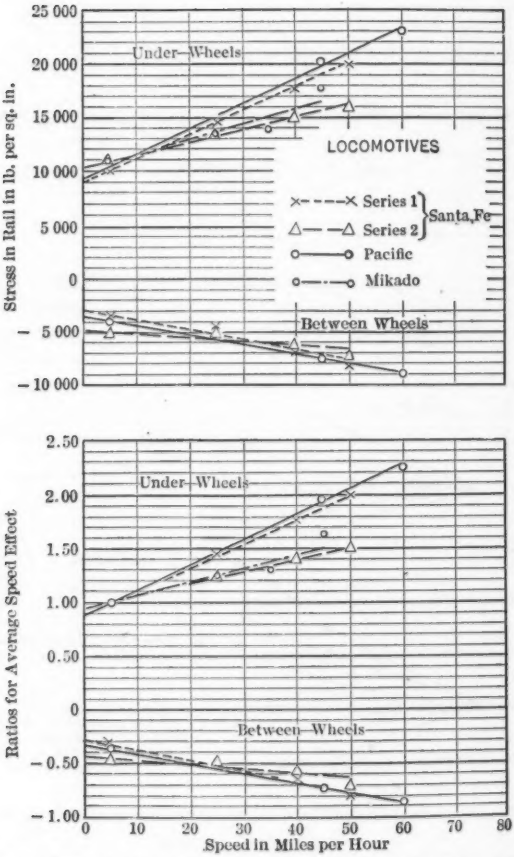

FIG. 29.—AVERAGE STRESSES AND RATIOS FOR AVERAGE SPEED EFFECT FOR THE TENDER WHEELS OF THE THREE TYPES OF LOCOMOTIVES.

and the other drivers overbalanced there is some transfer of pressure through the equalizer bars, tending to reduce somewhat the stresses due to counterbalance, but the effect is not very definite and seems to be uncertain. The stress due to counterbalance increases much faster than the increase in speed, though not always as fast as the square of the speed. The average increase in stress at the several drivers due to counterbalance effect, as indicated by the ratios in the diagrams, for a common speed of 50 miles per hour over the stress at 5 miles per hour is about 90% for Series 1 and 80% for Series 2 (average 85% for the Santa Fe type locomotives used); 30% for the Pacific type; and 60% for the Mikado type. The increase in stress at the main driver in each case is greater than this average, and with the Santa Fe type very much greater.

Points representing the calculated counterbalance effect ratio are also given in Figs. 25, 26, 27, and 28; they are based upon the counterbalance weights given in Tables 1, 2, and 3 without consideration of the effect of the planes of rotation of the rotating parts being in different planes or of other disturbing elements. It will be noted that in a number of cases there is a considerable discrepancy between the observed and the calculated ratios.

The following general observations are made:

It is evident that there is a decided advantage to the track in making the counterbalance of the several drivers differ but little from each other and from that condition which will give the best results, even though opposing conditions of counterbalance in the main driver and the adjoining drivers may have some neutralizing effect. An underbalance on one driver and an overbalance on an adjoining one will give a very undesirable cumulative effect.

It is of course to be expected that when the locomotive is working the downward pressure of the main driver will be increased over that obtaining when the steam is shut off as was the case in the tests here discussed.

For the Santa Fe type locomotives tested the stresses at the main driver were much greater than at the other drivers.

Considering the stresses developed in the tests it is not strange that great injury to track is done by poorly balanced locomotives run at high speed. Even at lower speeds, where kinking of rail does not result, the punishment of the track is much greater than will be caused by well-balanced locomotives. The effect of counterbalance and speed is to add greatly to the load to be carried by rail, tie, and ballast.

Effort may well be made to reduce the counterbalance effect on stress in track by use of the best methods of design of locomotive and by the use of material which will permit a minimum of counterbalance effect in both rotating and reciprocating parts.

It is important that care be taken to determine the actual weights and position of counterweights and the actual properties of the side rods and connecting rods. Care should be taken to learn whether the assumed division of load among the drivers in the completed locomotives is obtained.

Locomotives will give very different stresses in rail at the different wheels according to the wheel spacing, the division of load, and the effect of adjoining wheels.

It is apparent from analysis that for the spacing of wheels in the three types of locomotives the stress at the trailer under static load or at low speeds will be relatively large if the weight on the trailer is greater than, say, 75% of the average weight on drivers; and the tests would indicate that for locomotives with even fairly good counterbalancing a discrepancy at low speeds between the stress at the trailer and the stress at a driver, due to a relatively heavy load on the trailer, may be expected to exist also at higher speeds.

It was found that the wheels of the tenders of the different types of locomotives gave quite different effects of speed on the stress in rail.

Attention may well be called to the method herein used in calculating the stress in rail for a combination of driver loads. The method ordinarily adopted in taking into account the counterbalance effect uses the dynamic augment for the given driver only. In getting the stress-producing bending moment in the rail, however, it is necessary to take into account the dynamic augment also of the adjoining drivers. With the main driver underbalanced and the adjoining drivers overbalanced the pressures given by the adjacent drivers are especially influential and the effect of the combined loads should not be overlooked. It should be added, too, that the effect of counterbalancing upon bending moment in rail is different from the effect upon rail depression and pressure on rail—these must be calculated separately.

In the discussion of counterbalance, and the calculation of the stress produced in the rail, no attempt has been made to go into the complications of the problem involved in the yielding of the locomotive springs and of the track acting as a spring, the effect of the rotating parts not being in the same plane, and other disturbing elements.

The tests were made on 85-lb. rail. It is felt that the effect of speed and counterbalance in producing stress in rails of other weight will follow in general the results found with the 85-lb. section. The increase in stress at a given speed over the stress at 5 miles per hour may be considered to be produced by additional loads at the drivers, due to speed and counterbalance, and the amount of these additional loads may be calculated by the use of the analytical methods outlined in the report. The loads thus found for speed and counterbalance effect

may be used in judging of the effect of speed and counterbalance with rails of other sections. The calculations for stress in a section may be made on the basis of the analysis for bending moments given in the first progress report, the section modulus of the given rail being used in calculating the stress developed by the bending moment found.

It is evident that wheel spacing, distribution of load among drivers and trailer, and counterbalancing have a marked influence upon the stresses developed in rail and also in the track structure below the rail. Adequate consideration therefore should be given to these elements in designing locomotives if the track is not to be called upon unduly to carry loads and to resist stresses which are unnecessary or excessive. The uncertainty which may exist concerning exact conditions of counterbalance is a matter which warrants greater attention.

III. Track Depressions.

18.—Depression of Track under Load and Modulus of Elasticity of Rail Support.—In the first progress report of the Committee the general question of the depression of track under load was considered and the effect of the make-up and condition of the track structure upon stresses in rail and distribution of load among the ties was discussed. In connection with the tests to determine the flexural action of ties in track (presented under "IV.—Depression, Flexure, and Bearing Pressure of Cross-Ties"), made since that report was prepared, tests have been made to obtain the depression of the track under the conditions which obtained when these tests of ties were made. A purpose of making these profiles of rail depression was to determine the proportion of the load applied to the rails which may be considered to be taken by a single tie. The tests served also to show the relative effects of different amounts of load and something of the general condition of the track.

Under the best conditions, with freshly tamped track, the depression at any tie may be expected to be nearly proportional to the load applied to the rail and likewise proportional to the load taken by the individual tie. For track not recently tamped or in poor condition there will be a slight play between the tie and the ballast along parts of its length, and part of the resistance before the tie takes bearing along its length will be due to the bending of the tie under the action of the lighter loads. These and other influences found in track not in the best condition make the line representing the relation of track depression to applied load vary from a straight line through at least a part of its length.

In Fig. 30, the relation between tie depression and load on tie for track in best condition is illustrated at (*a*). The vertical distances represent the depression of rail; the horizontal distances are proportional to the load on the track. This condition gives a constant modulus

of elasticity of rail-support—the term defined in the first progress report as the pressure per unit of length of each rail required to depress the track one unit and which was found to be of considerable service in analytical investigations.

At (*b*) is illustrated the case where a light load produces considerable depression and greater loads result in additional amounts of depression which are proportional to the increments of load. The distance from the origin to the point where the line passing through the points intersects the vertical axis may be considered to represent in part the play or space between the bottom of the tie and its bed when

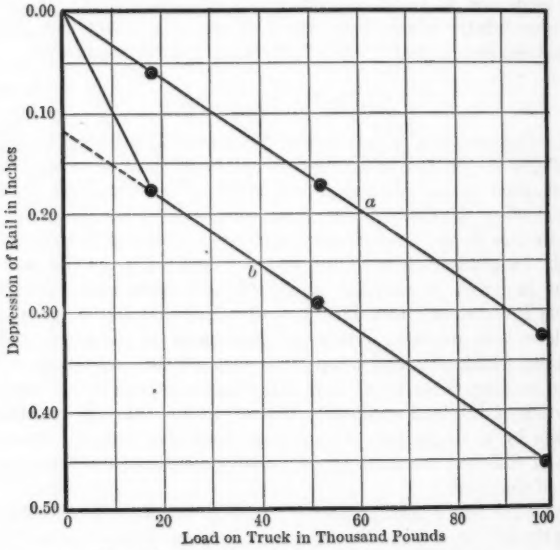

FIG. 30.—TYPICAL LOAD-DEPRESSION DIAGRAM.

the tie is not under load, though of course there is some bearing resistance by the tie for track depressions less than the amount of this intercept, and a part of the total play may be between the rail and the tie. In general the direction of the line through the points obtained by the several loads represents the load-depression relation and is closely parallel to the line found for well-tamped track. For general purposes the direction of this part of the line may be used in determining the value of the modulus of elasticity of rail-support.

19.—Track-Depression Tests on Illinois Central Railroad.—In the tests of track depression made in 1918 the load was furnished by cars loaded in such a way as to give the desired weight on the truck at one

end of the car. The end of the car to be used in the test was weighed on track scales. In the use of the data of the tests it is assumed that each wheel of the car truck carried one-fourth of the weight so found. In the tests on the Illinois Central Railroad three loads were used, 100 000, 53 000, and 18 000 lb. on a single truck; that is, 25 000, 13 250 and 4 500 lb. on each of the four wheels of the truck. The smallest load was taken as being sufficiently heavy to bring the tie to a full bearing on its bed and to eliminate any play which may exist between rail and tie and tie and ballast. The wheel base of the truck was 5 ft. 6 in. The distance between trucks (31 ft. center to center for the car giving loads of 100 000 and 53 000 lb. and 29 ft. for the one giving 18 000 lb.) was such that the load on the trucks at the farther end of the car did not have a large effect upon the track depression at the middle of the length of the car. The center of the truck was placed at the middle of the length of the rail, except on Section *K* and on cinder ballast (alternate joints) where the load was placed at the quarter points of the rail.

The level bar described in the first progress report was used in taking the levels along the rails for zero load and for the other loads from which the track depressions were computed. The method of making a test was the same as that described in the first progress report. A fixed reference stake was placed 80 in. from the rail and levels were carried from this bench mark to the rail by means of the level bar for each set of levels. A set of levels along the portion of the rail measured was first taken for zero load. One of the loads was then applied and levels were run over the stretch of rail, and this was followed with measurements at the remaining loads. In all cases levels were run on both rails.

The tests were made on the main line of the Illinois Central Railroad about two miles north of Champaign, Ill., on the track previously prepared for the track tests and on the sections of track marked *B*, *C*, and *K* in Fig. 26 of the previous report. The ties were the 6 by 8-in. by 8-ft., sawed, oak ties furnished for the test track in 1914. The rail on Sections *B* and *C* was the 85-lb. rail of Am. Soc. C. E. section, the same as was in the track in the previous tests, and that on Section *K* was the 125-lb. rail also used in the other tests. Besides these tests, a test was made on the north-bound freight lead shown in Fig. 26 of the previous report, which has 85-lb. rail and 12 in. or more of cinder ballast, and the usual run of hewn oak ties with a few sawed ties.

The main track had not been tamped for some time, a year or more, and although only passenger trains used it ordinarily, the track was not in good surface condition. The track depressions found and the flexural action of the ties go to show looseness and play between tie and ballast. Attention should be called, too, to the scantiness of the shoulder

of ballast on the outer side of the south-bound track (see Fig. 43), particularly on Section *B*, which gave little support to the ties at this end. Altogether, however, the track was not in bad riding condition and may be said to be representative of much well-made track at times when it has received the effect of traffic over a considerable period after tamping. At one location, *B*-2, the track was tamped slightly between tests but not enough to improve its condition materially.

On Section *B*, tests were made at two locations (adjoining rails) which will be designated *B*-1 and *B*-2. This section has 12 in. of stone ballast. On Section *C*, the two locations (also on adjoining rails) will be designated *C*-1 and *C*-2. This section has 6 in. of stone ballast. At Section *K* the ballast is 24 in. deep.

Figs. 31, 32, 33, 34, and 35 give the track-depression profiles. The loads given are the total loads on a single truck. The levels were taken for a length of 40 ft. or more, depending upon the location of the joints, and the results for the full length are given for Location *K*, *C*-1, *C*-2 and cinder ballast; for the other locations the profiles for a shorter length are shown, including all the ties which carry loads of any amount. In Figs. 32 and 33 load-depression diagrams have been plotted below the profiles for different points along the rail, the horizontal distances being proportional to the load on the truck; the intercept on the vertical axis of the straight line used is taken as the vertical play in the track. In several cases the measurements for the east rail were found to be inconsistent and unreliable, and these have been discarded.

In making the calculations for tie reactions, the amount of the play found from the load-depression diagrams was subtracted from the observed tie depression; the total load was divided by the sum of the net depressions for all the ties carrying load; the product of this quotient and the net depression of a tie was taken as the load or reaction of that tie. If the play found for different parts of the track-depression profile was fairly uniform the average play was used. In some cases the play differed considerably at points along the profile and it was necessary to use that found for each tie. Generally speaking, the length of rail considered included all the ties showing a positive net depression. As there was some negative reaction on ties beyond these limits the actual load on the ties considered was in reality greater than the applied load.

In Table 13 the tie reactions are given for the several tests. The values are given in terms of the load on truck at the end of the car used. The ratios given in the table are more convenient for making comparisons than weights. Values found from the higher loads are given; for the low load the effect of the tie play is so great that comparison based on this load would not be especially useful. If gross depressions had

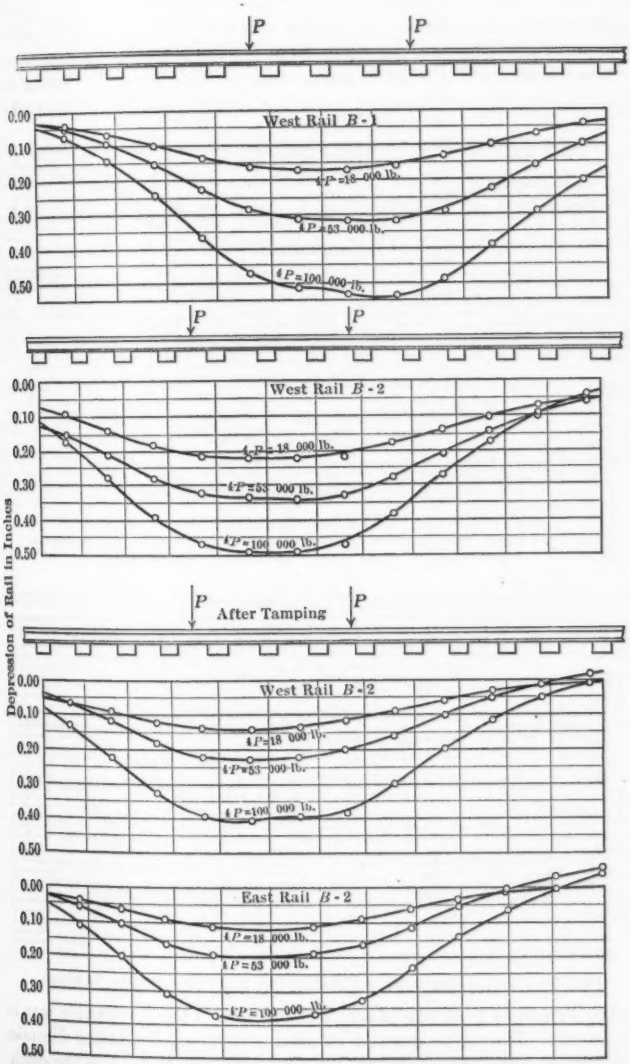

FIG. 31.—TRACK DEPRESSION PROFILES ON ILLINOIS CENTRAL RAILROAD.

been used instead of net depressions the tie reactions throughout the middle of the track-depression profile would be smaller than the values given in Table 13 and those away from the loads would be greater.

The values in Table 13 indicate that for this two-axle loading and 85-lb. rail the tie reaction at the wheel is from 13 to 16% of the load on

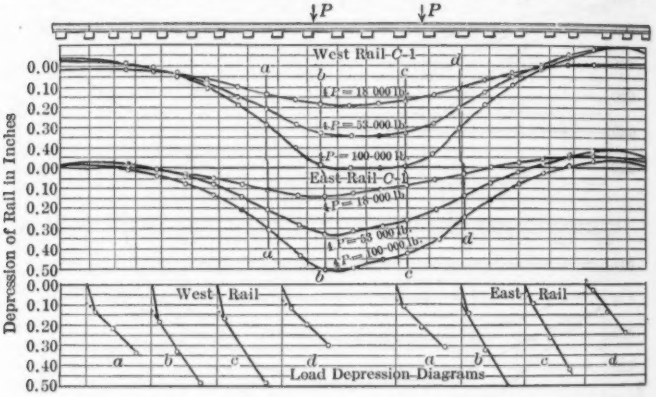

FIG. 32.—TRACK DEPRESSION PROFILES ON ILLINOIS CENTRAL RAILROAD.

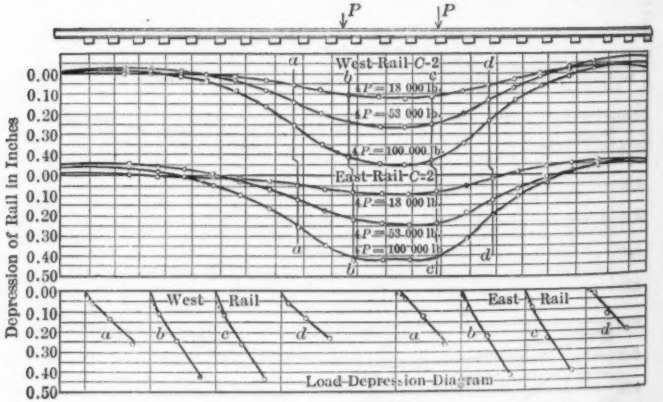

FIG. 33.—TRACK DEPRESSION PROFILES ON ILLINOIS CENTRAL RAILROAD.

the truck, and at a point midway between wheels the tie reaction may be 1½% more. The value derived by means of track-depression formulas found by the analysis given in the first progress report for the conditions of this test is about 15% at the wheel and 16% midway between

wheels. The depression away from the wheels also agrees fairly well with that determined by the analysis. Still farther away, in the region where negative pressures have more influence in the analysis, it cannot be expected that the conditions of the track will be those assumed in the analysis.

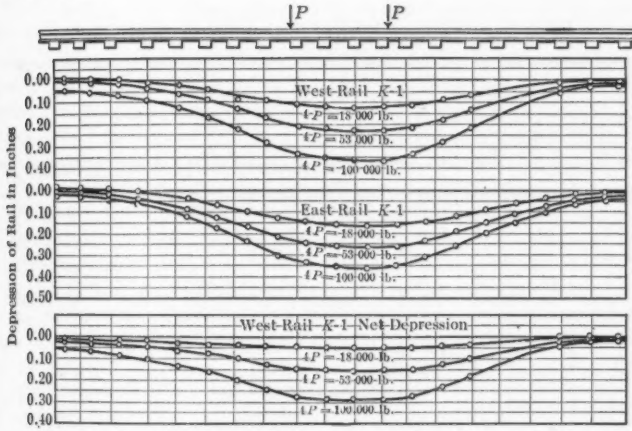

FIG. 34.—TRACK DEPRESSION PROFILES ON ILLINOIS CENTRAL RAILROAD.

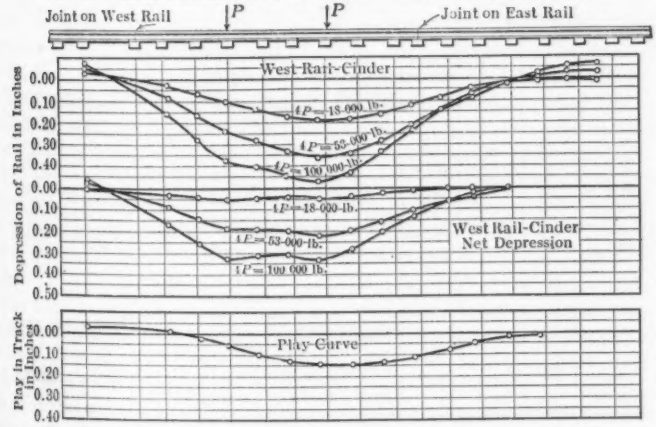

FIG. 35.—TRACK DEPRESSION PROFILES ON ILLINOIS CENTRAL RAILROAD.

The values at and between loads given in Table 13 are somewhat greater for a truck load of 53 000 lb. than for 100 000 lb., although the difference in ratios is not large. For the axle load of 18 000 lb. the ratio for the maximum tie reactions is still somewhat greater. If the partial

resistance corresponding to the first part of the depression of the track is taken into consideration, the difference in the ratios corresponding to the three loads will become still less. For most purposes it is sufficient to consider that the proportion of load taken by a tie is independent of the total load applied.

As would be expected, the stiffer rail at Location *K* gives a wider distribution of load and a smaller maximum tie reaction. By the analysis for the conditions of the test, the reaction of the tie at a wheel is calculated to be 13% of the load on the truck. The depression profiles for this location are regular, and nearly the same for the two rails, as

might be expected with the stiffer track. On the other hand, the depression profiles for the freight track (cinder ballast) are irregular and uneven, the load-depression curves deviate considerably from a straight line, and the conditions are such as to give uneven loads on ties and to increase the stress in rail over that which would be found in good track.

The amount of the play between rail and tie and tie and ballast shown by the load-depression diagrams ranged from 0.06 to 0.18 in. (untamped track). On some of the sections, the amount varied considerably throughout the length carrying the load, say, 0 to 0.10 in., showing a great diversity in the bearing of the several ties. The condition of the bearing at the two sides of the track also differed considerably. These facts will be found to be significant when the discussion of the flexure of ties is made. It is true, of course, that in places away from the test sections, which had ties of uniform dimension and spacing, the track play was greater and more variable, as could be observed at the time trains were passing.

The values of u, the modulus of elasticity of rail-support, obtained from the test data for Locations B and C, range from 900 to 1 300 lb. per in. per in., with an average value of 1 100. The value at Location B-2, after the track had been tamped slightly, was about 1 200. The value at Location K (24 in. of ballast not recently tamped) was about 1 200. The value for the test on cinder ballast was 1 000, although it must be borne in mind here again that this track was not in good surface.

20.—*Track Depression Tests on Chicago, Milwaukee and St. Paul Railway.*—The tests for track depression on the Chicago, Milwaukee and St. Paul Railway were made in the manner already described for the tests on the Illinois Central Railroad. The loads on the truck at one end of a car were 100 000, 68 000, and 37 000 lb., which were assumed to be equally divided among the four wheels of the truck. The wheel base of the truck was 5 ft. 6 in., and the distance center to center of trucks was 28 ft. 10 in., 29 ft., and 25 ft. 11 in., respectively, for the cars giving the loads named above. As the rails were laid with alternate joints, the center of the trucks was placed at the quarter points of the rail.

The tests were made on the main line of the Milwaukee Division and on the Janesville Division, a branch line. The tests on the main line were made at two points (see Fig. 36), Q on the east-bound main track about a mile south of the station at Deerfield, Ill., (east in railroad parlance) and O and P on the east-bound main track a quarter of a mile nearer the station. In each case passing tracks permitted traffic to be routed so that the tests were not interfered with. The tests on the Janesville Division were made on the single track a mile west of the station at Libertyville, Ill.

On the main-line track at Deerfield (called by the Railroad Company Class A track) the rail was 100-lb., Am. Soc. C. E. section. The ties were mostly hewn red oak ties, zinc-chloride treated, though perhaps 20% were sawed ties which had replaced old ties. The hewn ties were variable in width ranging from 8 to 11 in.; the sawed ties were 8 in. wide. Part were 7 in. thick and 8 ft. 6 in. long and part 6 in. thick and 8 ft. long. The ties were spaced about 20 in. center to center (twenty to a rail length of 33 ft.). The spacing was fairly uniform. The ballast was bank-run gravel, 45% of which passes a ¼-in. sieve. The depth of ballast was about 36 in. At the side next the other main track, and also on the other side of Location *Q*, the surface of the ballast ran level from top of tie of track tested to top of the tie of the adjacent track. At Location *O* and *P*, on the outer side the ballast extended at level of the tie for a distance of 15 in. from the end of the tie and then sloped down 10 in.

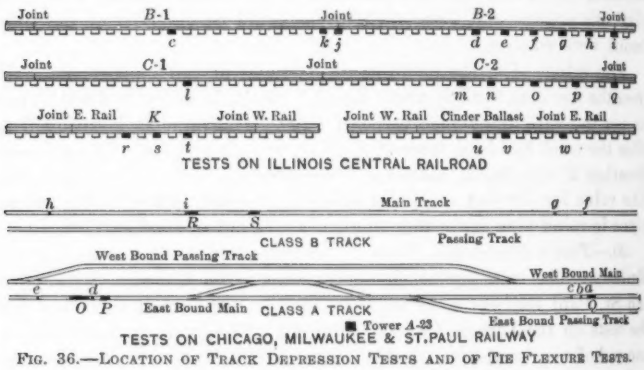

FIG. 36.—LOCATION OF TRACK DEPRESSION TESTS AND OF TIE FLEXURE TESTS.

in 2 ft. (see Fig. 44), so that in all cases there was adequate opportunity for full support at the end of the tie. The track surface was in good condition, but it had not been tamped for some months. The roadbed at Location *Q* was not much above the level of the ground; Location *O* and *P* was on an embankment of considerable age.

On the branch-line track at Libertyville (called by the Railroad Company Class B track) the rail was 75-lb., Am. Soc. C. E. section. The ties were mostly hewn soft wood ties, quite irregular in shape, but 20% were sawed ties, both oak and soft wood. The sawed ties were 6 by 8 in. by 8 ft., and the hewn ties were somewhat wider. The ties were spaced twenty to a rail length of 33 feet. The ballast was gravel about 36 in. deep. Due to the existence of the passing track (see Figs. 36 and 44) there was little slope on one side of the track. On the other the ballast sloped from 3 in. below the top of tie at its end at a 1:2 slope, forming a less effective support than was found on the other side. The

track surface was in indifferent condition, the track not having been tamped for some time. At places this track had been built over soft spots, which at times had given trouble by subsidence.

Fig. 37 gives the track-depression profiles at Locations *Q* and *P* of Class A track and Fig. 38 at Location *O*. In the diagrams load-depression diagrams at several points of these profiles are also given. The play in track denoted by the intercept at the vertical axis, found as shown in Fig. 30, was determined for a number of points along the rail; in Fig. 37 (and also in Figs. 39 and 40) a second set of profiles for one test has been drawn by plotting the net depressions found by deducting from the measured depression the play so determined. It will be noted that the profile of measured depressions is somewhat irregular and unsymmetrical. The profile of net depressions is more nearly regular and symmetrical, and the final load-depression ratio shows nearly the same stiffness throughout. This illustrates the variations in tie-bearing at points close together even in good track in fair condition; it has significance in relation to bearing pressure of tie, tamping conditions, and stress developed in the rail. The amount of the track play ranges from 0.02 to 0.17 in. in the track-depression profile of Figs. 37 and 38. In these tests, also, the depressions for one rail differed considerably from those for the other, though the net depressions were in close agreement.

Figs. 39 and 40 give the track-depression profiles on Class B track and also load-depression diagrams for several points along the rail for these tests. This track shows more irregularity along the length of the rail and more variation in play than was found in Class A track. At the point of maximum depression on the west rail of the upper profile of Fig. 39 the tie had been cut into by the tie-plate about $\frac{1}{2}$ in., a fact which was brought out when the load was applied.

In Table 14 the tie reactions are given for the several tests on the Chicago, Milwaukee and St. Paul Railway, the values being in terms of the load on one truck. The values at and between wheels range from 10 to 15 per cent. Class A with the heavier rail has a somewhat lower tie reaction than Class B.

The value of u, the modulus of elasticity of rail-support obtained from the track-depression profiles, is about 2 000 lb. per in. per in. for Class A track, and 900 for Class B track. The value for Class A track is materially higher than that found in the Illinois Central tests. Several factors may contribute to this—longer ties, broader ties (more bearing area in a rail length), gravel ballast instead of limestone ballast, greater depth of ballast, or better supporting conditions at ends of ties.

IV.—Depression, Flexure, and Bearing Pressure of Cross-Ties.

21.—The Cross-Tie and Its Action under Load.—In railroad track of ordinary construction the cross-tie performs many important func-

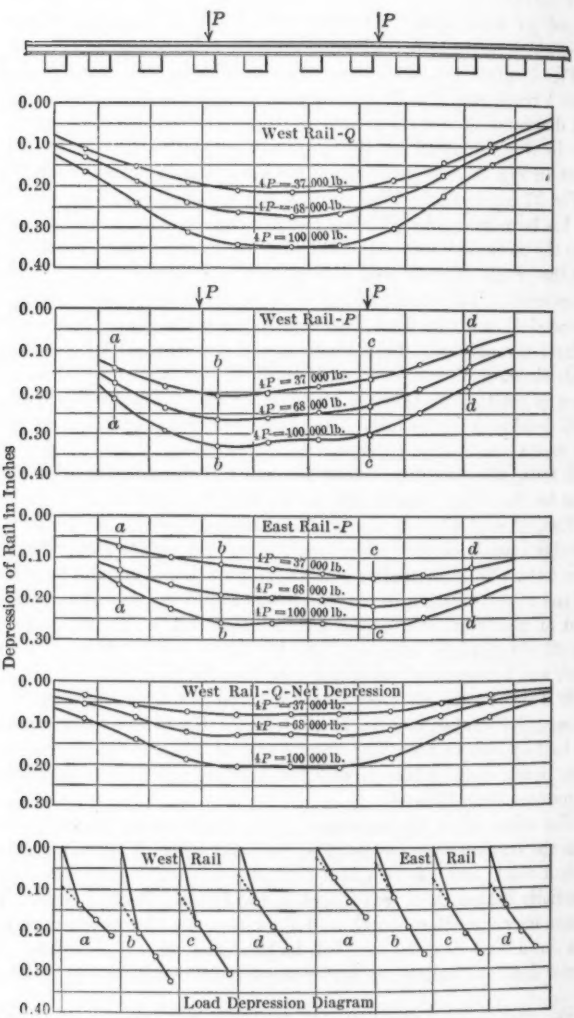

FIG. 37.—TRACK DEPRESSION PROFILES ON CHICAGO, MILWAUKEE AND ST. PAUL RAILWAY: CLASS A TRACK.

tions—it bears the load transmitted from the rails, makes a definite connection and spacing between the two lines of rails, transmits the pressure to the bed of ballast and by its properties as a beam distributes this pressure along its length. It thus is subject to compression under and in the vicinity of the rail, to tension or compression as a structural connection between rails, and to beam action in giving distribution to bearing pressures along its bed. Of these the last bears the most important relation to the problems here considered; the others will not be treated at this time.

The cross-tie has many features which make it an acceptable part of ordinary track construction. It has great flexibility in meeting the

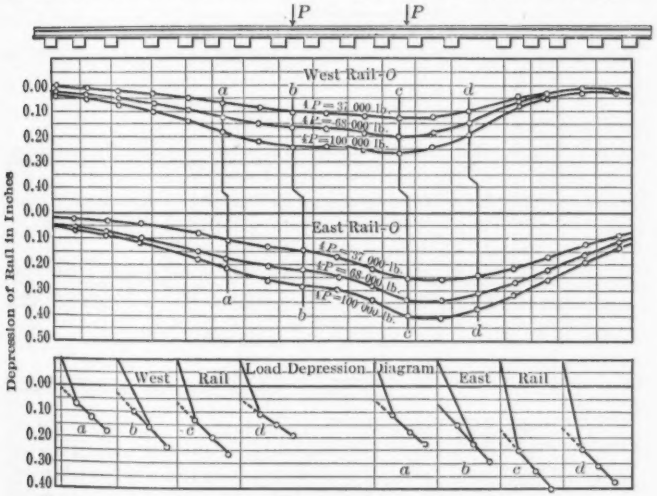

FIG. 38.—TRACK DEPRESSION PROFILES ON CHICAGO, MILWAUKEE AND ST. PAUL RAILWAY: CLASS A TRACK.

varied and diverse requirements of both ordinary and unexpected track and load conditions. It gives facility in providing, maintaining, or shifting the gauge, line, and surface of track and in tie renewals and other changes in track, and is accepted as an economical and reliable element of ordinary track construction. It is known to be effective under very imperfect track conditions, being used where great variation of size and quality of tie, depth, and quality of ballast, and condition of tamping of track may be expected to cause marked differences in the requirements put upon it. Quantitative data on the flexural action of the tie and the way its loads are distributed along its bed, as well as of its depressions under load, therefore, should be of considerable value.

22.—Method of Attacking the Problem.—The problem to be considered relating to the action of the tie involves the distribution and intensity of the bearing pressure on its bed along its length and also the bending moments and stresses developed by this pressure and the load applied through the rails—these to be determined for the limits and ranges of values included in the variety of conditions to be found in track. This information will throw light on the question of the intensity of pressure on the ballast and also on the design of the tie, particularly if a tie of new form or dimensions or of materials other than wood were to be considered. The question of the intensity of pressure on the ballast for differing conditions of track tamping or of

track maintenance has a bearing on the questions relating to track ballasting. Even bearing pressures give good riding quality to the track, while spots with less and greater resistance to depression increase the stress in the rail and other parts of the structure and cause more rapid deterioration in the quality of the track. The determination of bending moments and stresses is closely related to various other parts of the problem.

A study of methods which may be used in attacking the problem of determining the distribution of the bearing pressure along the length of the tie will bring out the difficulties attending the experimental work. There is a great diversity of variations—differences in bearing pres-

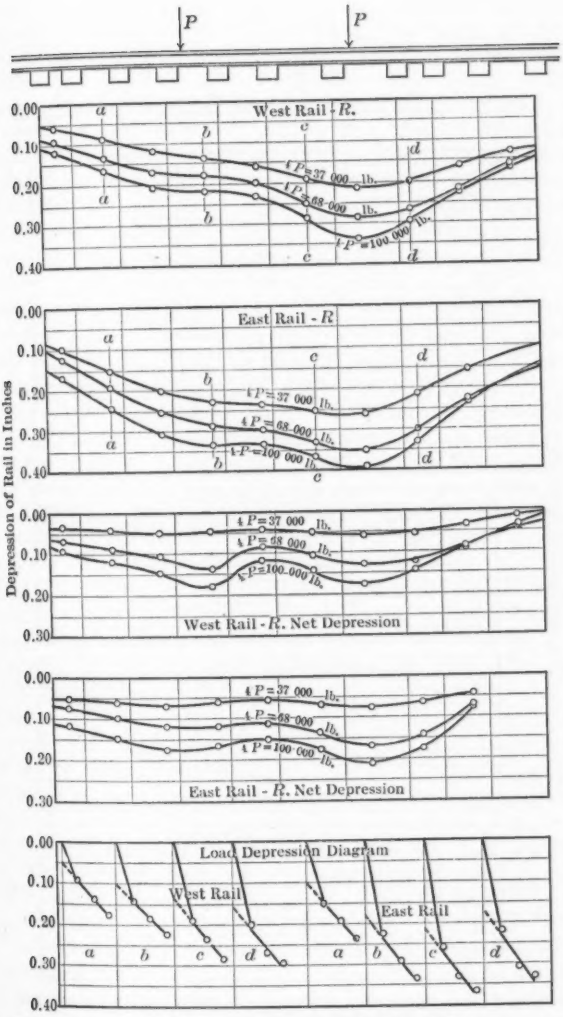

FIG. 39.—TRACK DEPRESSION PROFILES ON CHICAGO, MILWAUKEE AND ST. PAUL RAILWAY: CLASS B TRACK.

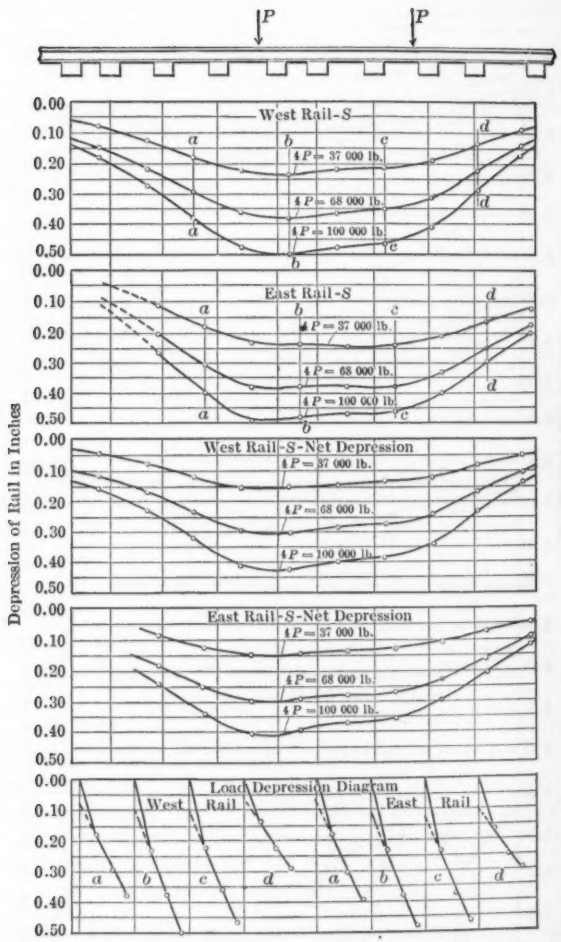

FIG. 40.—TRACK DEPRESSION PROFILES ON CHICAGO, MILWAUKEE AND ST. PAUL RAILWAY: CLASS B TRACK.

sures across the width of the tie and along the tie; play between tie and its bed, which varies in different parts of the length of the tie and varies greatly with the nature of the tamping and the effects of the action of traffic; unequal stiffness (yieldability) of the ballast at various points—these illustrate difficulties encountered in the problem. The use of pressure-measuring devices between tie and ballast—such as the pressure capsule described in the first progress report—gave general information and served fairly well in the laboratory investigation; but the number required in the length of one tie to give the needed information and large number of ties required to determine the run of conditions, the disturbance of the track through inserting the instruments with the uncertainty as to whether the resulting condition of track was representative of normal track, and the chance for instruments becoming deranged in the interval elapsing until the track would seem to have reached normal conditions, all combined to make the direct measurement of bearing pressure impracticable as a method of getting the information desired on this subject. Of indirect methods the measurement of the strains or deformations along the length of the tie as produced by its bending was considered, but variations in the properties of the wood, especially under field conditions, as well as uncertainties of other kinds, rendered this method impracticable.

A trial was then made of a method of measuring the curve of flexure of the tie as it bends under the applied load in the track and making use of the relations between flexure, bending moment, and load as derived by mechanics of materials for a beam having the properties of the timber tie used. The measurements made included also the depression of the tie below its original position, as produced by the compression of the ballast and roadway or other conditions. This method is manifestly imperfect, having a number of limitations and uncertainties, but it is not difficult to use, the track conditions may be taken as they are found, and the number of tests may be chosen to cover a variety of conditions of ties and track. The measurement of tie depressions also gives information of value in the study of stresses in track. The method was used, therefore, as being the best known method applicable to the conditions of the track tests. It has given data of value, although certain uncertainties and inconsistencies are discernible in the results, especially those resulting from the local bearing compression in the vicinity of the rail. The details of the method will be described in Article 23. The consideration of the bending moments will be given in a succeeding article. Here it is only necessary to note that the curvature of the curve of flexure of the beam at any point is proportional to the corresponding moment and stress—the sharper the curve the greater the moment and the stress.

23.—Method of Making Tests.—In measuring the depression and flexure of the ties a stiff wooden reference bar (see Figs. 41 and 42) was placed under the rails between ties and close to the one on which measurements were taken. At each end of this bar was attached an iron cross-bar about 2 ft. long, the ends of which rested on two substantial stakes well driven into the ground, giving a firm support to the apparatus. These stakes were 7 ft. or more from the center of the track. Attached to the main bar were iron brackets (shown in Fig. 41) which projected over the tie. To each bracket was attached a piece of small angle iron; on this was bolted an Ames dial gauge which reacted against a tack driven at the mid-point of the width of the tie and served to measure the depression of the tie at that point. The arrangement of the attachment permitted adjustments vertically and horizontally.

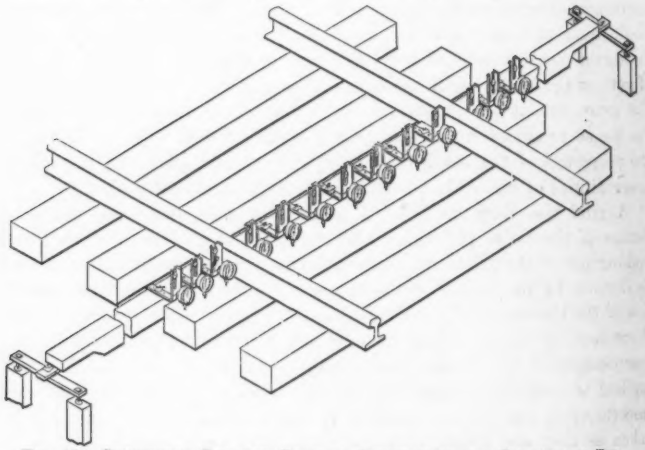

FIG. 41.—REFERENCE BAR FOR TEST OF DEPRESSION AND FLEXURE OF TIE.

Before applying a load the dials were adjusted to read zero. For each load applied the dials were read to the nearest half-thousandth of an inch. When the load was removed, a small depression was indicated by the dials and they were again set at zero. The same load was again applied, the process being continued until three consistent sets of readings were obtained. The average of these sets of readings was used.

In the tests on the Illinois Central Railroad nine dial gauges were used—five between rails and two on the outer side of each rail. This number of points was found not to determine the curve of flexure as accurately as was desired, and in the later tests made on the Chicago, Milwaukee and St. Paul Railway the number of dials was increased to thirteen, seven between rails and three on the outer side of each rail; this

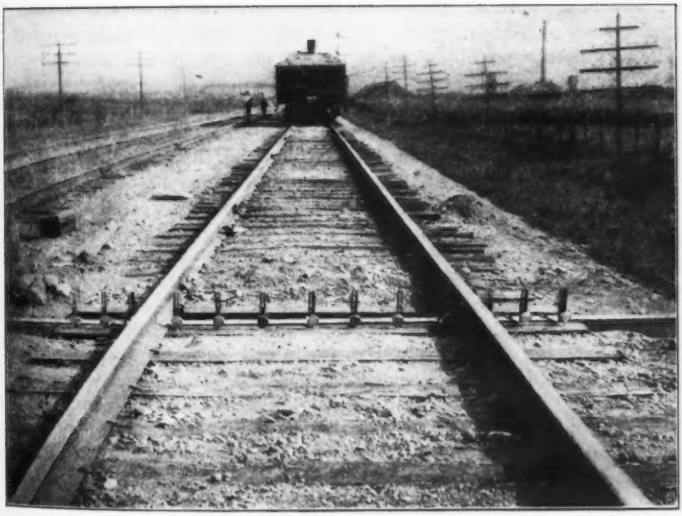

FIG. 42.—REFERENCE BAR FOR TEST OF DEPRESSION AND FLEXURE OF TIE.

improved the character of the data very much. In each case the dials next the rails were 1 to 2 in. away from the base.

The loads were given by means of loaded cars, as already described for the tests of track depression. The three loads on a single truck (two axles) were 18 000, 53 000, and 100 000 lb. on the Illinois Central Railroad and 37 000, 68 000, and 100 000 lb. on the Chicago, Milwaukee and St. Paul Railway. The leading wheels of the truck carrying the load were placed directly over the tie under test. The amount of the load considered to bear on the tie under test was taken from the results of the track-depression tests at the given location. The smallest load used was generally more than sufficient to overcome the play between tie and ballast, though of course this should not be taken to mean that under this condition the pressure on the bed of ballast is distributed uniformly along the length of the tie. The largest load used gave a tie reaction considerably less than that which would be caused at and between drivers by an ordinary Mikado or Santa Fe type locomotive. In the study of the data the largest load was generally used, though the smaller loads have given valuable information on the action of the tie.

The readings in all the tests checked very closely and the results are concordant. The effect of the rail bearing in compressing the fibers adjacent to the rail is unknown, but the reading of the dials next to the rail must include the general depression and bending of the tie and also a third element—the influence of the local downward compression of the tie due to the bearing pressure of the rail; the latter will have to be taken into account in interpreting the curves of flexure as related to bending moments and stresses.

The form of reference bar given in Fig. 41 is the improved form used in the tests on the Chicago, Milwaukee and St. Paul Railway. The bar used in the earlier tests was lighter and less stiff. In the use of this apparatus it should be noted that it was necessary to remove the ballast between the tie to be tested and an adjoining tie to a depth of 4 or 5 in. below the top of tie. This probably had little effect upon the action of the tie during the tests, although under continued traffic of no greater loads the effect might be noticeable.

24.—*Location and Description of Track.*—Fig. 36 gives data on the location of ties at which measurements of depression and flexure were made, together with condition of the track. The letters *B*, *C*, and *K* designating location on the Illinois Central Railroad refer to the sections of track north of Champaign, Ill., shown in Fig. 26 of the first progress report. The ties on the main-line track were the sawed oak ties (6 by 8 in. by 8 ft.) furnished for the test track in 1914. The tests on the freight lead were made on two hewn oak ties about 6½ by 8¾ in. by 8 ft. and a sawed oak tie 6 by 8 in. by 8 ft. The location of the tests on the Chicago, Milwaukee and St. Paul Railway has already been described under "Track Depression Tests on the Chicago, Milwaukee

and St. Paul Railway". Sawed ties were selected for test because of their uniformity of cross-section. The ties on Class A track were 7 by 8 in. by 8 ft. 6 in.; those on Class B track 6 by 8 in. by 8 ft. Tie-plates 8 by 9 in. were on all ties in the Class B track.

Attention should be called to the condition of the cross-section of track at the test locations given in Figs. 43 and 44. In some of the sections on the Illinois Central Railroad it may be seen that there is a scant amount of ballast above the bottom of the tie near its ends, particularly on the outer side of the track. On the Chicago, Milwaukee and St. Paul Railway, as has already been pointed out, the sections are such that there was opportunity for full support at the end of the tie. The condition of the track surface has been described under "Track Depressions"; it may be well again to call attention to the fact that the track in all the test locations had not received a general tamping for some time and that in some locations it was apparent that the track was in indifferent condition as to surface and tamping, and thus furnished opportunity to determine depressions and flexure under other than best conditions, and really under conditions frequently found in practice.

25.—Diagrams of Depression and Flexure and Their Significance.— Figs. 45 to 54 give the depressions and flexure of the individual ties at a truck load of 100 000 lb. The load on a single tie, as determined by the track-depression profiles, ranged from 11 000 to 18 000 lb., perhaps averaging 15 000 lb. The vertical scale is relatively large, thus bringing out the curvature, which of course is slight, as is the case with any short stiff beam. The tie depression under this load varies from 0.35 to 0.5 in. Figs. 55 and 56 give composite diagrams of the flexure of several ties at the same location and which have the same general characteristics of flexure; the differences in depressions and the tilting of the ties are not here considered—the diagrams are plotted with reference to a line drawn from rail to rail. In Fig. 47 curves are drawn to represent the depressions and flexure for all three truck loads. The dotted lines given in this diagram (and in the other diagrams), obtained by a method described subsequently, are intended to represent the position of the ballast bed under the tie when there is no load on the tie; the dotted lines given are for the tie "before tamping".

An examination of the diagrams of depression and flexure brings out a variety of conditions. It will be observed that there is bending of tie in every case, though the form of the curve varies greatly. It is evident that there must be great differences in the way in which the bearing pressure varies along the length of the tie under the conditions to which ties are subjected. In many ties there is play between the tie and its bed at one point or another or even over a considerable portion of its length, which not only gives unevenness of track depression but increases the intensity of bearing pressure at some point along the tie

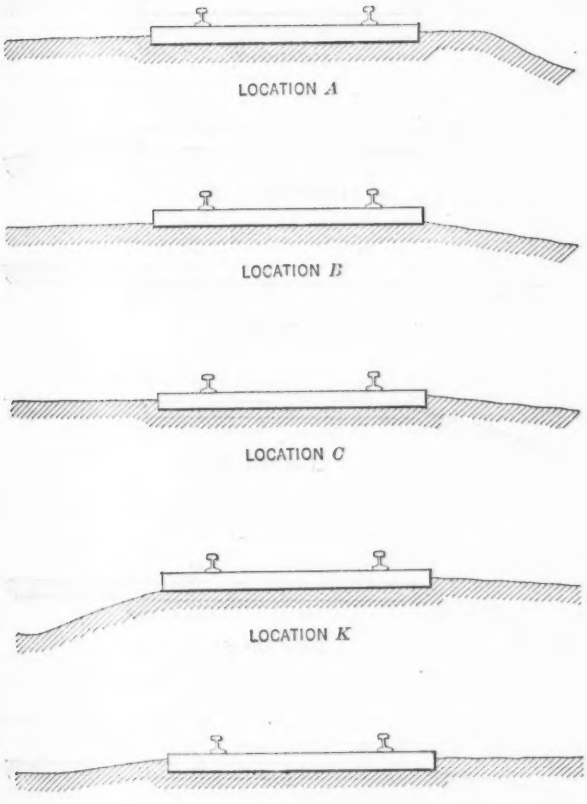

FIG. 43.—CROSS-SECTIONS OF TRACK ON ILLINOIS CENTRAL RAILROAD.

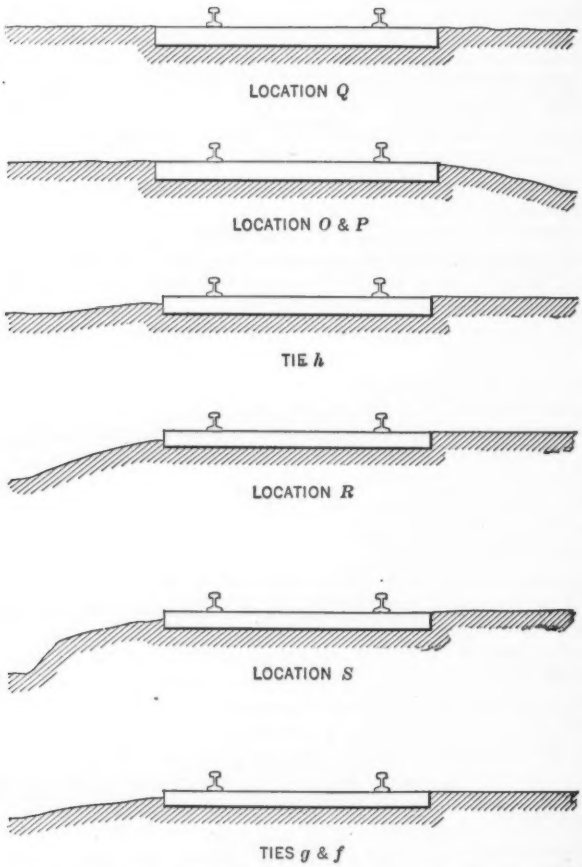

FIG. 44.—CROSS-SECTIONS OF TRACK ON CHICAGO, MILWAUKEE AND ST. PAUL RAILWAY.

and gives added bending stresses in the tie. It is clear that there is a great variety of distribution of bending moments along the tie—the bending moment at a section at the middle of the tie may be positive in one tie and negative in another, as is shown for Tie *o* in Fig. 50 for "after tamping" and "before tamping". Attention should be called to the fact that the tamping done was slight and at the ends of the tie only; the term "after tamping" should not be taken to mean a general tamping.

The conditions just referred to are ordinarily termed endbound and centerbound. It will appear that the latter condition is very common; in fact, the upward curvature at the middle and a large negative

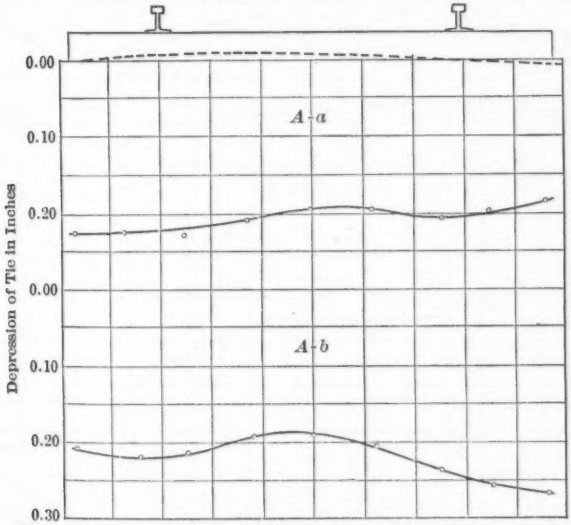

FIG. 45.—DIAGRAM OF DEPRESSION AND FLEXURE OF TIES, ILLINOIS CENTRAL RAILROAD.

moment accompanying it may be expected in most track after traffic has had its effect upon track condition. The immediate effect of tamping a tie in ballast already well compacted being to change the bearing conditions along the tie (the compacting of the ballast in the tamping having only a secondary effect), a fresh tamping or a change in the place of tamping makes a marked effect on the flexure of the tie. The ties in Location *B* were found to be loose at their ends under the conditions of the track in service, with a resulting flexure curve shown in Figs. 46, 47, and 48 for Ties *c* to *k*. The part of these ties outside the rails was then tamped slightly, not vigorously, and the curve in Fig. 49 for Tie *g* slightly tamped shows that the bearing is largely at the

ends of the tie. Change in position of the ballast under traffic conditions will soon modify the distribution of bearing pressure. Even though the tamping is restricted to a space adjacent to the two rails, the depression of the track under load may be expected to bring some bearing pressure at the middle of the tie length, and the action of a repetition of applications of pressures of high intensity over the tamped portion will cause a movement of the ballast and a redistribution of bearing pressures.

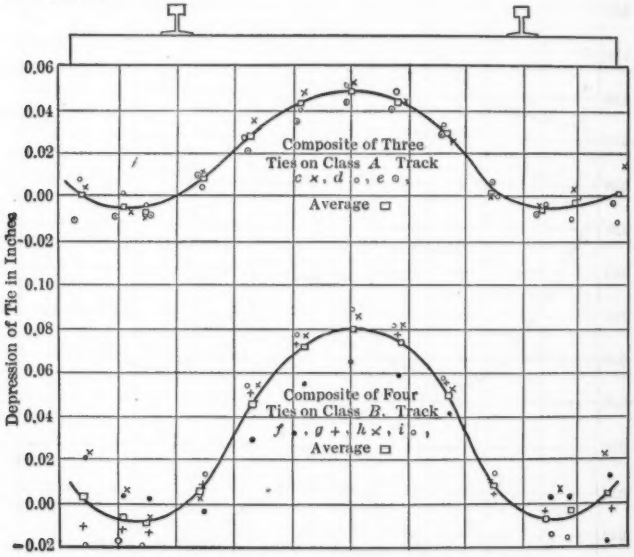

FIG. 56.—COMPOSITE DIAGRAMS OF TIE FLEXURE, CHICAGO, MILWAUKEE AND ST. PAUL RAILWAY.

The condition of the ballast section at and beyond the end of the tie seems to have a modifying influence upon bearing conditions. The scantness of the shoulder in Section *B* of the Illinois Central Railroad evidently contributed to the loose ends and play of many of these ties, especially those the looseness of which was noticeable by inspection; the effect of this probably becoming apparent only after traffic had produced appreciable changes in the position of the particles of ballast. The more complete support at end of tie in the ballast section on the Chicago, Milwaukee and St. Paul Railway gives conditions which are quite different.

The initial position of the ballast bed with respect to the bottom of the tie for the compact condition of ballast existing in the track tested

may be found approximately by the following method. In any diagram of depression and flexure (as, for example, Fig. 47), for each point along the tie and each depressed position, lay off a horizontal distance proportional to the load producing the given tie depression. The points so measured for the three loads used will be found to lie almost in a straight line. Produce such a straight line to intersect the vertical line through the initial position of the point on the tie. This intersection would be the initial position of the ballast bed under the point on the tie if the bearing pressure was uniform along the tie. A second approximation (which it is not generally necessary to make) may be made by assuming that at any given point the intensity of the bearing pressure accompanying each load varies as the vertical distance from the point just found to the position occupied at the given load. This method will locate quite closely the initial position of the bed for track with well compacted ballast. The bending of the tie to fit minor depressions, such as that which may exist directly under the rail, is not taken into account; this would modify the results but slightly. The dotted lines given in the diagrams, obtained in the manner described, may then be expected to represent fairly closely the initial position of the bed under the tie. Play is given by the space between this line and the tie. It will be seen from the diagrams that the ties which show large upward curvature at the middle have their beds curved in

the same manner; in other cases the bed at the middle is much lower than at the ends of the tie—the play between tie and bed being at the ends in one case and at the middle in the other.

As the amount of depression affects the modulus of elasticity of rail-support, u, it may be expected that the condition of tie and ballast will be influential factors. In determining u, the play in track depression was omitted from the values, though of course it enters into the development of stresses in the rail and is known to produce higher stresses than would otherwise occur, especially if the play varies from tie to tie. The bending of the ties, however, and especially that under the rail, tends to make low values of u. Another element contributing toward the higher value of u in the Chicago, Milwaukee and St. Paul Railway track, already referred to, seems to be the gravel ballast; there are fewer voids and a greater cross-section of material to take the load and therefore the amount of compression in the ballast may be expected to be less. The modulus of elasticity of the limestone used on the Illinois Central Railroad is less than that of the gravel of the Chicago, Milwaukee and St. Paul Railway.

Attention is called to the fact that the deflections in the flexure curve of the 7 by 9-in. ties are much smaller than those in the 6 by 8-in. ties; for the same loading the deflections may be expected to vary inversely as the moment of inertia of the section and the moment of inertia of the 7 by 9-in. tie is nearly 70% greater than that of the 6 by 8-in. tie. It may be added that the greater stiffness of tie should help in making more uniform pressures along the length of the tie.

The joint ties, j and k (see Figs. 36 and 48) were chosen for test because they were particularly loose and showed much play. The effect of tamping on this tie is very noticeable. The condition of the joint Tie i (see Fig. 48) is not especially different from the other ties in the vicinity.

The composite diagram for the ties on cinder ballast gives a good appearance, symmetrical and with apparent good end bearing, but it should be noted that these curves are not plotted from gross depressions; the individual ties give markedly different curves, tilting first to one side of the track and then to the other. This is due not only to the ballast and condition of tamping, but to the fact that the ties were unevenly spaced and did not always lie at right angles to the rails. The change from the greatest depression occurring at the end of a tie at one side of the track to the greatest depression at the other side of the track within a short distance was not confined to the freight tracks and cinder ballast. The tilting of the tie to one side of the track, however, was more common where the shoulder of ballast was scant.

The effect of the greater length of tie in Class A track will be considered in Article 26.

26.—Bearing Pressure and Bending Moment.—If the intensity of the tie reaction were directly proportional to the measured tie depression it would be easy to find the distribution of the tie reaction along the length of the tie by the use of the diagrams of tie depressions already given. Two variations from this law of distribution of pressure are known to exist; (*a*), due to the condition of ballast bed under the tie the unloaded tie may not touch its bed at all points, and (*b*), the ballast may be more compact and stiffer at one point than at another. Most of the uncertainty due to the first condition may be overcome by the use of the dotted line in the diagrams of tie depression as expressing the initial position of the tie bed; there may be a further depression in the bed due to the bending of the tie immediately under the rail, as shown in Fig. 54 (left end of Tie *h*). The dotted lines of the diagrams generally indicate a centerbound condition; this gives a bending moment at the middle of the tie when it is brought to a full bearing and increases the bending moment at all loads and also results in an increase of intensity of bearing pressure at the middle. A permanently formed depression at the rail acts to relieve the intensity of tie reaction there but increases the bending moment at this point when a load is applied which brings the tie down to full bearing. The second condition, that not giving direct proportionality between depression and intensity of bearing pressure, is particularly evident in freshly placed ballast. In well compacted ballast the variation from proportionality may be expected to be slight. Immediately after tamping, the bed may be somewhat stiffer at the point of tamping; as the effect of tamping disappears through the movement of the particles of ballast, the yieldability of the ballast under load, that is, the modulus of elasticity of the mass, tends to become more uniform along the length of the tie. By taking into consideration the effect of variations in these conditions the diagrams of tie depression and flexure will be found useful in indicating the range of variation of bearing pressure and bending moment.

It will be of interest to consider a variety of assumed distributions of bearing pressure (tie reactions) and the resulting distribution of bending moments. Fig. 57 gives a number of hypothetical cases. Uniform pressure shown at (*a*) cannot be expected. For a few inches at the end of the tie the bearing pressure must be small. The flexure of the tie itself will also produce a variation from uniformity of pressure. At (*b*) is shown a diagram indicating the influence of these factors when the initial bearing is fair and the stiffness of the bed is uniform along the length of the tie. At (*c*) the distribution is sometimes thought to exist when the tie is tamped for a foot or so on each side of the rail. Diagram (*d*) gives the distribution for freshly tamped sand ballast as found by laboratory measurements with pressure capsules—little pressure was here found at the middle of the tie; (*e*) assumes the

principal bearing to be at the rails tapering off in each direction; (*f*) assumes maximum intensity at the end of the tie and (*g*) at the middle; (*h*) represents a form of distribution for the centerbound tie, somewhat as was found for the medium load in some of the tests; (*i*) represents the distribution for an endbound tie; (*j*) may be considered as representative of the pressures under a well tamped tie in compact ballast after traffic has begun to have an effect. It is possible that at the point of greatest depression, as immediately under the rail, a permanent depression will be formed and the tie will not touch the bed until it has bent considerably at this point. This condition tends to give a decreased intensity under the rail, as shown at (*k*), but the effect of this on the distribution is not great.

TABLE 16.—BENDING MOMENTS IN TIE FOR ASSUMED DISTRIBUTIONS OF BEARING PRESSURE.

W = Total load, in pounds, carried by one tie. Moment is then given in pound-inches.

Distribution as designated in Fig. 57.	8-FT. TIE.		8-FT. 6-IN. TIE.		9-FT. TIE.

j	+1.4 *W*	−2.4 *W*	+1.9 *W*	−1.8 *W*	+2.4 *W*	−1.0 *W*
k	+1.6 *W*	−1.9 *W*	+2.1 *W*	−1.1 *W*	+2.6 *W*	−0.4 *W*
l	+4.9 *W*	+5.2 *W*	+5.7 *W*	+6.0 *W*	+6.4 *W*	+6.7 *W*
m	+2.4 *W*	+0.6 *W*	+2.1 *W*	+1.4 *W*	+3.6 *W*	+2.2 *W*

The relative magnitudes of the bending moments at points along the tie are shown for these cases by the diagrams at the right in Fig. 57. Table 16 gives, for the distributions of bearing pressure assumed in Fig. 57, the values of the bending moment at two sections of the tie and for three lengths of tie. W is the total load on the tie in pounds and the moment is expressed in pound-inches. It is seen that there is a considerable range of values of the moments, both at the middle of the tie and at the rail. It is also to be noted that a slight change in the distribution of the intensity of bearing pressure along the tie makes a relatively large change in the amount and distribution of the bending moments.

A study of the flexure curves of the ties tested in track and a comparison with flexure curves corresponding to the distribution of moments given in Fig. 57 show that a variety of conditions of tie

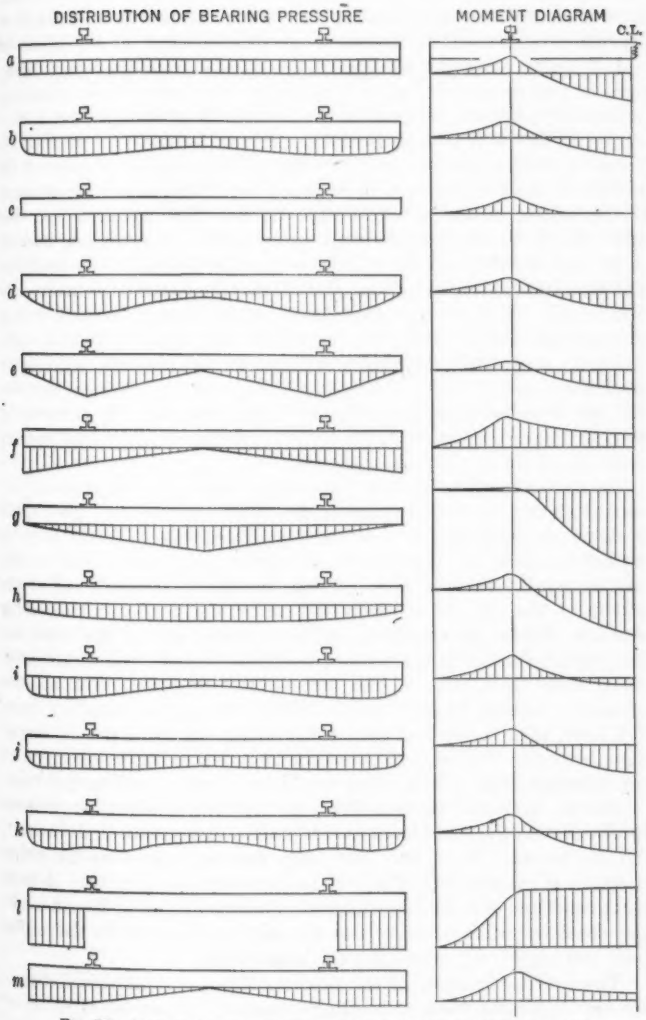

FIG. 57.—HYPOTHETICAL DISTRIBUTIONS OF BEARING PRESSURE AND CORRESPONDING MOMENT DIAGRAMS FOR TIE 8 FT. LONG.

bearing may exist. Even in well-tamped track the uniform distribution of bearing pressure indicated at (*a*) cannot occur. The intensity of bearing pressure will be greater near the rail than at the middle or end of the tie since the bending of the tie will result in larger depressions at that point. The more flexible the tie, the greater the variation in intensity; likewise, the stiffer the ballast, the greater the variation—all resulting in increased intensity of bearing pressure at the rail. Such a condition gives a smaller value of the bending moment at the middle of the tie than would be found for uniform bearing pressure. If the ballast at the middle of the track is less compact than elsewhere the difference becomes more pronounced. The bending moment at the rail for this condition is less than for the endbound condition. The condition given at (*c*) in Fig. 57 may be expected to merge into that at (*d*). With a concentration of pressures near the rails it may be expected that a permanent depression will soon be formed under the rail, a greater depression all along the tie will then occur upon the application of the heavy loads, and the bearing pressures will be distributed more uniformly along the tie. A permanently formed depression under the rail will increase the bending moment in the tie at the section under the rail.

In centerbound track, for the smaller loads, the tie reactions are carried mostly in a short space at the middle of the tie. These small loads act to bend the tie downward at its middle to fit the shape of the bed (as given for Tie *i* by the dotted line in Fig. 48); only a small load is needed to give this bending, particularly as the bed at the middle of the tie will be depressed under the action of the bearing pressure. Under the conditions of the tests with centerbound track, the load required to bring the tie to a bearing under the rail was probably not greater than 10% of the 100 000-lb. load used. The negative moment produced by this small load is, of course, relatively large. The loads used in the test give full bearing along the tie, the depressions from the original position of the bed (dotted line in the diagram) not differing greatly from what would be found in well-tamped track.

For an endbound tie (see Tie *q* in Fig. 50), the bending moments developed with the small loads are all positive (curvature all downward), and for unusual conditions they may remain positive at the higher loads, as is instanced in Tie *o* after tamping (see Fig. 50). A more usual condition for what is commonly included as an endbound condition develops positive moments at the middle of the tie for the smaller loads and negative moments for the larger loads.

The curves of flexure of the ties (see Figs. 45 to 52) give information on the distribution of bending moments. Since the curvature of the curve of flexure of the tie varies as the bending moment develops, the distribution of bending moment along the tie may be determined if the curvature at various points is known.

If R is the radius of curvature of the curve of flexure at a given point, in accordance with beam theory the expression for the curvature at that point is $\frac{1}{R}$ and the bending moment M will be $\frac{E\,I}{R}$, where E is the modulus of elasticity of the wood and I is the moment of inertia of the cross-section of the tie. It had been expected that the data of tie flexure would be of such nature as to give fairly accurate means of determining the moments developed in the ties and their distribution. It has been found that the local vertical compression of the wood at and near the rail, due to the bearing pressure of the rail, affects the depressions of the points near the rail (the amount was small, but the flexure of the tie was also small) to such an extent as to modify the form of the curve of flexure and thus throw some uncertainty on the radii of curvature derived therefrom, even at the middle of the tie. The values found for sections at the middle of the tie are fairly accurate; those at the rail are somewhat less reliable. The average of the values found will be useful for comparison. It seems probable that measurements made at the middle of the edges of the tie would give data of more value.

The curves of flexure of the various ties, obtained from the measurements, have been studied; the results give at least a qualitative distribution of the moments. To determine the modulus of elasticity of the wood, ten of the ties tested in the track were tested in the laboratory. The ties were considered to have a moisture condition similar to that existing when they were in the track. The tie was supported as a beam of 90-in. span, two equal loads applied at points 25 in. from the center, and the center deflection read over a chord of 40 in. The resulting values of the modulus of elasticity, calculated by the formula for deflection of beams, ranged from 1 000 000 to 1 400 000 lb. per sq. in., for the oak ties, averaging 1 250 000 lb. per sq. in. For the soft wood tie from Class B track, the value was 800 000 lb. per sq. in.

Table 17 gives values of bending moments in the tie at its center and at the rail, determined from the flexure curves by the method above described for the data of the ties tested in the track. The moments are expressed in pound-inches, W being the load carried by the tie, in pounds. As has been stated, it is to be expected that the method used is subject to error, and some of the values of the bending moment at the rail seem very high. The data are useful, however, in giving quantitative values which may be developed in track service.

It will be seen that negative bending moments as great as $-4.5\ W$ lb-in. were developed at the center of the tie, W being the load carried by one tie. For well tamped track and track kept in good condition, the negative moment will be considerably smaller, and for such conditions a value as low as $-2.0\ W$ may be expected as the upper limit. Excessive bearing pressures at the ends of the tie and needed strength

TABLE 17.—VALUES OF BENDING MOMENTS IN TIE DETERMINED FROM CURVES OF FLEXURE.

W = Total load, in pounds, carried by one tie. Moment is then given in pound-inches.

in handling it make it seem desirable to provide also for a positive bending moment of $+ 1.0\ W$ at the center.

For uniform bearing along the tie, the value of the bending moment at the rail would be about $+ 2.0\ W$ lb-in. for ties 8 ft. 6 in. long. In Table 17 values as high as $+ 4.8\ W$ and $+ 6.0\ W$ are found. It would appear that bending moments even larger than these values may be expected in track considered to be in ordinarily good condition. For first-class track in excellent condition it seems probable that a bending moment $+ 2.5\ W$ at the rail should not be exceeded. The high values of bending moment at the rail obtained from the flexure curves are not readily explained; it seems probable that the depression of the fibers of the wooden tie under and near the rail, as indicated in Fig. 58, results in a greater flexure of the tie than would otherwise occur. Even though the bending moment found by the process used is, by reason of this condition under the rail, greater than that which exists by virtue of the bearing pressures between the rail and the end of the tie, the reduction in resistance to flexure produced by excessive depression of the fibers under the rail may be as much or more than the

discrepancy in bending moment, and hence values of the bending moment such as those given previously are not too large for use under the conditions found with wooden ties.

The bearing pressure under the tie of course will vary in intensity along its length. A study of the data of the tie flexure tests indicates that the maximum bearing pressure per unit of length of tie, under static loading, will not ordinarily exceed twice the average bearing pressure over the length of the tie, and that for track in good condition the maximum will be less than one and one-half times the average. These values relate to bearing pressures per unit of length of tie; as will be shown in the next chapter of the report the variation in intensity of pressure from the edge to the middle point of the width of the tie is considerable and the maximum intensity at the middle of the width may be much greater than the average.

It may be noted that the heaviest load on a tie generally occurs under the closely spaced drivers of a heavy freight locomotive, and the static load on one tie may be found approximately by dividing the weight on a driving axle by the number of ties which come within a driver spacing.

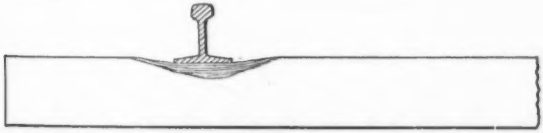

FIG. 58.—DIAGRAM SHOWING LOCAL DEPRESSION OF FIBERS UNDER RAIL.

It should be noted that the present discussion relates to static loading—no allowance has been made for the effect of speed, counterweight, and impact in increasing the loads on the tie; these should be considered in finding the bending moments, stresses, and bearing pressures which may develop in track service.

V.—TRANSMISSION OF PRESSURES IN BALLAST.

A.—Analytical Discussion.

27.—Introductory.—Crushed rock, gravel, cinders, burnt clay, slag, and sand are the materials commonly used for ballast. These materials are practically devoid of cohesion, at least when first placed. Earth and clay possess cohesive properties in some degree. Non-cohesive materials consist of separate pieces which will be hereafter referred to as grains. The grains are of irregular size and shape, and when first placed form a loose mass which cannot carry load without considerable readjustments of their relative positions. Under repeated applications of load, or other working, the grains are rearranged so that the mass becomes quite compact.

By reason of its structure, a load is transmitted through a non-cohesive granular mass from grain to grain by contact pressures. The

distribution of pressure is made through chains of grains in contact which lie between the load and a point in the ballast. Consideration will be given first to special forms of grains and then to the general form found in ballast.

28.—The Transmission of Load Through a Pile of Cylinders.—Assume that the cylinders are piled as compactly as possible. There are three cases to consider: First, when the cylinders are frictionless; second, when the coefficient of friction is equal to or greater than tan. 30°; third, when the coefficient of friction is between these two conditions.

In the first case, since there is no friction between the cylinders, the pressure at the point of contact must be normal to the surfaces in contact; that is, the line of action of the pressure must pass through the centers of the cylinders in contact. All the pressure, therefore, is transmitted through two chains, as shown in Fig. 59. It is evident that without adequate lateral support, the column of cylinders carrying the load will buckle, resulting in a rearrangement of the whole mass. The load-carrying capacity of a pile of frictionless cylinders is very small, because the only lateral forces which can be exerted are those due to the weights of the cylinders.

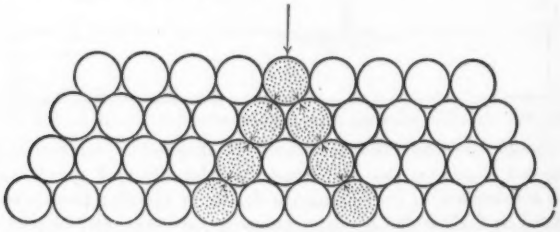

FIG. 59.—TRANSMISSION OF PRESSURES THROUGH PILE OF FRICTIONLESS CYLINDERS.

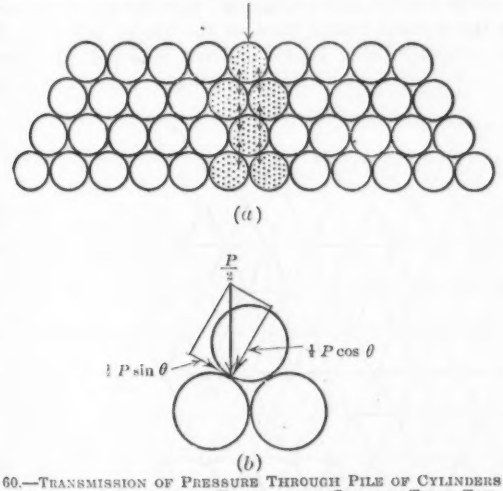
In the second case, when the coefficient of friction is equal to or greater than tan. 30°, all the load applied to the upper cylinder can be carried by the two cylinders below without the aid of lateral pressure. These in turn can be supported by one cylinder below them, as shown in Fig. 60 at (*a*). In this case there are no lateral forces developed or required for stability. That equilibrium will exist under this condition may be seen from the diagram at (*b*). The vertical force $\frac{1}{2}P$ may be resolved into two rectangular components. The ratio of the tangential to the normal component is

$$\frac{\frac{1}{2}P \sin. 30°}{\frac{1}{2}P \cos. 30°} = \tan. 30°$$

For values of the coefficient of friction less than tan. 30°, slipping will occur; for equal or greater values, equilibrium will exist.

In the third case, when the coefficient of friction is greater than zero and less than tan. 30° the distribution of load will be between the extreme conditions represented by the cases previously considered. The actual distribution will depend upon the value of the coefficient of



(a) (b)

FIG. 60.—TRANSMISSION OF PRESSURE THROUGH PILE OF CYLINDERS WHEN COEFFICIENT OF FRICTION IS EQUAL TO OR GREATER THAN TAN. 30°.

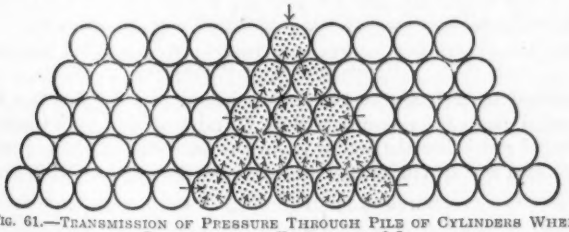


FIG. 61.—TRANSMISSION OF PRESSURE THROUGH PILE OF CYLINDERS WHEN COEFFICIENT OF FRICTION IS 0.2.

friction. As an illustration, the distribution of pressures in direction and magnitude when the coefficient of friction is 0.2 is indicated in Fig. 61. It will be noted that in this case lateral pressures are required in alternate rows in order to keep the mass in equilibrium.

It has been shown, then, that even when considering the distribution of pressure through a pile of equal-sized, incompressible cylinders, arranged symmetrically, the problem becomes so complex that it would be difficult to obtain results of general value. The complication is

caused by the effects of the lateral components of the pressures between the grains. This suggests that grains be assumed of such shape that there will be no lateral forces.

29.—The Transmission of Pressures Through a Pile of Grains in Which There are no Lateral Pressures.—To make the problem as simple as possible it will be assumed that the grains are of such shape that each grain rests on two grains and that the points of contact are always on the vertical center lines of the grains below, the distribution of the pressure being lateral and not longitudinal. Such a pile is shown in Fig. 62. One-half of the load applied to any grain is

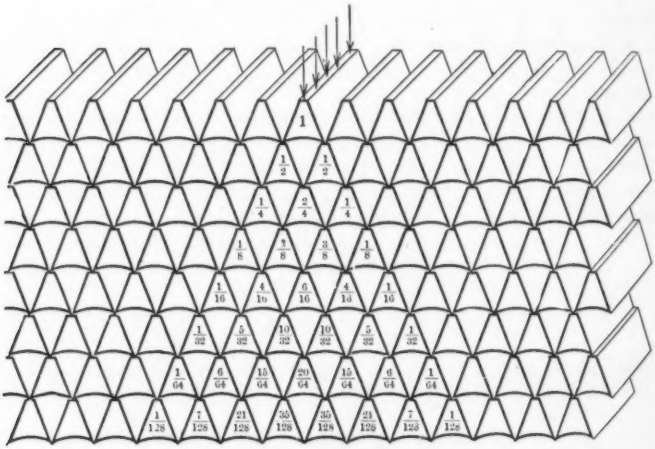

FIG. 62.—TRANSMISSION OF PRESSURE THROUGH PILE OF GRAINS WHEN NO LATERAL FORCES ARE DEVELOPED.

transmitted to each of the two grains below. In the first row below the loaded grain the pressure will be $\frac{1}{2}$ and $\frac{1}{2}$ of the applied load. In the second row below the loaded grain the pressures will be $\frac{1}{4}$, $\frac{2}{4}$, and $\frac{1}{4}$. In the third row it will be $\frac{1}{8}$, $\frac{3}{8}$, $\frac{3}{8}$, and $\frac{1}{8}$. In the nth row it will be:

$$\left(\frac{1}{2}\right)^n, n\left(\frac{1}{2}\right)^n, \frac{n(n-1)}{1\times 2}\left(\frac{1}{2}\right)^n, \frac{n(n-1)(n-2)}{1\times 2\times 3}\left(\frac{1}{2}\right)^n, \text{etc.}$$

That is, in any row, the pressures on the grains will be represented by the terms found by the expansion of the binomial

$$\left(\frac{1}{2}+\frac{1}{2}\right)^n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

For example, in the bottom row of Fig. 62,

$$\left(\frac{1}{2}+\frac{1}{2}\right)^7 = \left(\frac{1}{2}\right)^7 + 7\left(\frac{1}{2}\right)^7 + \frac{7\times 6}{1\times 2}\left(\frac{1}{2}\right)^7 + \text{etc.}$$

It can be shown that the distribution of pressure given by this equation when n is large is similar to that given by the curve known as the probability curve. The equation giving this distribution of pressure on any horizontal plane is

$$p = \frac{k p_0}{\sqrt{\pi}} e^{-k^2 x^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

in which p is the pressure at a horizontal distance x from the center line of the applied load, e is the Naperian base of logarithms, p_0 is the applied pressure and k is a function of the distance below the loaded grain. The form of the curves given by the equation may be judged from the three curves in Fig. 65.

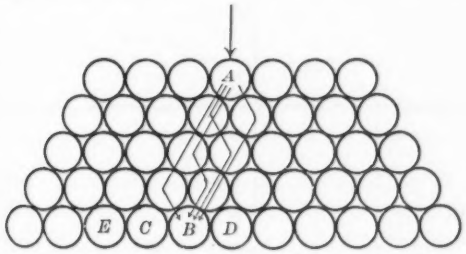

FIG. 63.—PATHS OF PRESSURE IN PILE OF CYLINDERS.

It is apparent that the condition assumed, each grain of ballast resting on the vertical center lines of two others, is a very special case. Results quite similar to those obtained above are found when the grains are of such form and arrangement that each grain rests on the vertical center line of three grains or of four grains. While the results found on such assumptions may not be quantitatively applicable, the analysis is of aid in forming a conception of the manner in which pressure is distributed and in giving a basis for expressing the results of experiments with ballast.

30.—Paths of Pressure and Law of Distribution of Pressure.—In general, there are a number of paths which the pressure may take as it is transmitted from one grain to another in the ballast; that is, there are a number of chains of grains in contact between the two grains under consideration. In Fig. 63 all of the possible paths of pressure between a loaded grain A and a grain B are indicated by lines. In this particular case there are four paths. Between Grains A and C there is only one path. Between A and E there is no path. Between A and D it can be shown that there are six paths. Referring also to Fig. 62 it will be seen that the number of chains of grains between A and B, C or D is the same as the numerator of the fractions representing

the pressures on the corresponding grains in the fourth row below the loaded grain.

In the preceding discussion, only grains of uniform size, special shape, and symmetrical arrangement have been considered. In ballast the grains have an infinite variety of sizes and shapes and are irregularly piled. Even with such irregular material the only method by which pressure can be transmitted from one grain to another not in contact with it is by means of chains of grains in contact with one another in the intervening space. Because of the irregular sizes, shapes and arrangements of the grains it is not possible to deduce a mathematical expression giving the amount of pressure transmitted from one grain to another in a particular case, but it has been found that by means of experiments and the use of the laws of averages good predictions may be made. The following discussion of the probable distribution of pressure from a loaded grain has been found to accord with experimental results.

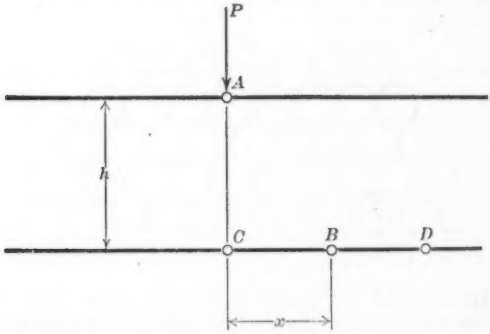

FIG. 64.—DIAGRAM SHOWING RELATIVE POSITIONS OF LOADED GRAIN AND POINTS ON HORIZONTAL PLANE.

Assume a load P applied to a grain A at a height h above a horizontal plane on which there is a grain B, as shown in Fig. 64. Between A and B there are various paths of pressure, or chains of grains, through which pressure is transmitted. The number of paths, or chains, will in general increase as B is taken nearer to C (the grain directly under A) and will in general diminish as the distance x from C is increased until a point D is reached beyond which there is no chain of grains transmitting vertical pressure. Between A and C the number of paths is a maximum for that depth. In view of the discussion in the preceding articles, it seems reasonable to assume that the pressure transmitted to any grain will in general be proportional to the number of chains of grains between the two grains, and it may also be expected that in general the number of chains of grains from A to any grain B on the

given plane at any distance x from the center, and hence the pressure transmitted, will vary in accordance with the law of distribution of pressure represented by Equation (14) on page 1531. This law of the distribution of pressure is confirmed by the experiments.

This equation, then, may be taken to express in a general way the probable form of the distribution curve of the vertical pressure transmitted from a loaded grain in ballast consisting of grains of irregular size and shape and placed in any manner. It should be noted that the transmission is considered to take place only laterally, that is, in a vertical plane, it being virtually assumed that other similar transmission exists in adjacent parallel vertical planes, as would be the case with a cross-tie and ballast. In the case of tie and ballast, due to variation in bearing pressure along the length of the tie, there will be some longitudinal transmission of pressure, tending toward greater uniformity of pressure parallel to its length, but this action may be considered separately. For a load applied to a single grain, instead of to grains along a line, the transmission horizontally would be in every direction and the distribution would give equal intensities along the circumference of horizontal circles, making an entirely different distribution from the case under consideration.

Since Equation (14) is an expression of the pressure on any grain in terms of the pressure on a single grain and does not give intensity of pressure, it is not in form for use. Assume the load to be applied to the ballast by means of a long narrow strip one unit wide. The pressure on any grain in the ballast will then be the sum of the pressures which would be found by use of Equation (14) applied to each grain in contact with the strip, and the resulting intensity of pressure at any point in the ballast may be expressed by an equation of the same form. Let p_a be the applied unit pressure, let h be the depth of ballast above a horizontal plane, and let x be the horizontal distance from the line of action of the applied load to the point on the horizontal plane at which it is desired to determine the intensity of pressure p, then

$$p = \frac{k p_a}{\sqrt{\pi}} e^{-k^2 x^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

k being a factor which depends upon h and must be found by experiment.

31.—Lines of Pressure.—In Fig. 65 curves have been constructed to represent the distribution of vertical pressure on several horizontal planes *ABC*, *DEF*, and *GHI*. The total areas under the curves represent the total upward reactions in the ballast on the horizontal planes. The upward reactions must be equal to the applied unit-load p_a when a section of ballast 1 in. long is considered. The areas under the several curves are therefore equal. These areas have been divided into a number of equal parts, each representing the same fractional part of the

reaction. The location of the resultant for each fractional area is noted on Fig. 65. Lines drawn through these points may be considered as lines of pressure representing the resultant fractional pressures.

The lines of pressure thus drawn are analogous to lines of force in a magnetic field, and the intensity of vertical pressure at any depth is seen to be equal to the number of lines of pressure passing through a width of 1 in. multiplied by the pressure which each line represents. For instance, if the lines are drawn representing pressures of 3 lb. and

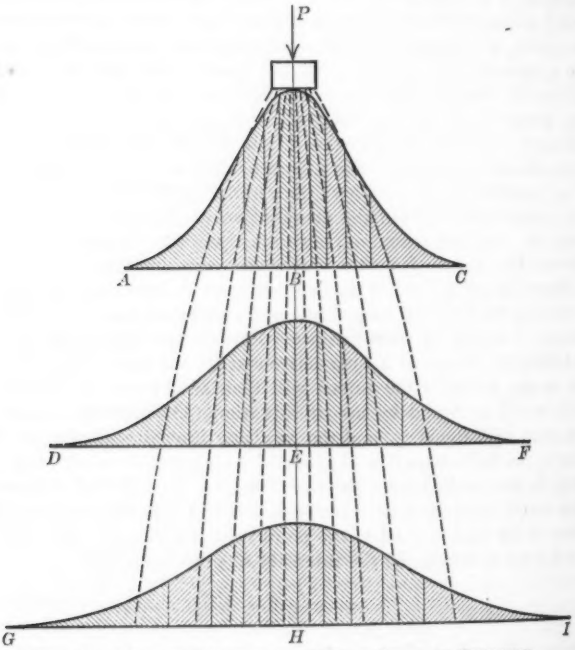

FIG. 65.—DIAGRAM ILLUSTRATING USE OF LINES OF PRESSURE.

at a given place on a horizontal plane four lines pass through a width of 1 in., the intensity of pressure is approximately $3 \times 4 = 12$ lb. per sq. in.

These lines of pressure will be found useful in explaining concentrations and distributions of pressure in ballast and in giving a conception of the manner of transmission of pressure.

32.—Rankine's Theory of the Relations of Pressures in a Granular Mass Devoid of Cohesion.—In 1856 Professor Rankine, from a study

of certain properties of stress relating to a infinitesimal wedge of granular material, enunciated several important theorems which have since borne his name. Several of these bear upon the discussion. They may be stated as follows:

Conjugate Stresses.*—*If any state of stress exists at a point in a granular mass, the stress acting on a plane through the point will be parallel to a second plane through the point, and the stress acting on the second plane will be parallel to the first plane. Stresses so related are called conjugate stresses.*

In Fig. 66, let the elementary prism be in equilibrium when acted upon by the stresses p parallel to AC, and the stresses q, direction unknown. It is required to find the direction of stresses q. Now the stresses p acting on the faces AB and CD must constitute a pair of forces in equilibrium; then to have equilibrium stresses q acting on the faces AC and BD must form a pair of forces in equilibrium, which can only occur when the stresses q are parallel to AB and CD.

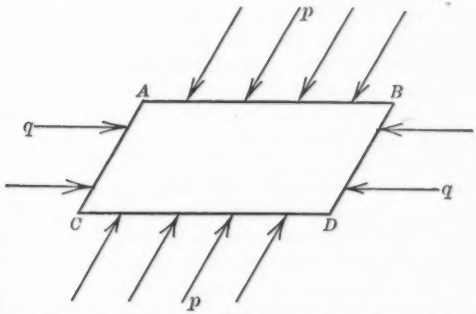

FIG. 66.—PARALLELOPIPED UNDER ACTION OF CONJUGATE PRESSURES.

Principal Stresses.*—*In any state of stress there is one pair of conjugate stresses at right angles to each other; i. e., there are two planes, at right angles to each other, on which the stress is normal only. Stresses so related are principal stresses.* For consider a plane at the point to rotate. There will be some position where the stress on the plane is normal; the plane at right angles will have a conjugate stress which is also normal. It can be shown that one of the principal stresses is the greatest stress and the other principal stress is the least stress at the point. Any possible state of stress can be completely defined by principal stresses.

* Taken with slight modifications from Ketchum's "Walls, Bins and Grain Elevators", to which the reader is referred.

The Ratio of Conjugate Pressures.—*The ratio of the intensity of the pressures on any pair of conjugate planes of pressure when motion is impending, is expressed by the equation:*

$$\frac{p_b}{p_a} = \frac{\cos.\theta - \sqrt{\cos.^2\theta - \cos.^2\phi}}{\cos.\theta + \sqrt{\cos.^2\theta - \cos.^2\phi}} \quad \ldots\ldots\ldots\ldots (16)$$

in which the stress p_a is greater than its conjugate unit stress p_b, θ is the common angle of obliquity which the stresses make with the normals to their planes, and ϕ is the angle of repose of the material.

When the angle θ is taken as zero, the conjugate stresses are perpendicular to their planes, hence p_a and p_b are the principal stresses. When motion is impending,

$$\frac{q}{p} = \frac{1 - \sin.\phi}{1 + \sin.\phi} \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which p and q are the greatest and least principal stresses, respectively.

Equations (16) and (17) express the relationships existing between conjugate pressures and principal pressures when motion is impending. The principal pressure q and the pressure p_b are *active pressures* developed by the application of their conjugate pressures. In case the resisting pressure is less than the active pressures the granular material will flow. In case the lateral pressures are greater than indicated by the equations, the granular mass will be in equilibrium.

33.—Conditions Accompanying the Application of Pressure by Means of a Tie.—In the preceding discussion it has been assumed that the pressure is applied only to a narrow strip. When the pressure is applied to the ballast by means of a tie the load is applied of course to the many grains in contact with the tie. It is common to consider that the intensity of pressure is the same all over the bottom of the tie and that it is normal to it (vertical). There is, however, a variation of the intensity of the pressure on the bottom of the tie due to the tendency of the ballast to move from the center to the edge of the tie when load is applied. Friction between tie and ballast develops pressures on the ballast which are not vertical. The maximum variation of pressure due to these causes will occur when the load is so great that the tie is being forced into the ballast. The following analysis will indicate the law of distribution under this condition of loading.

34.—Variation of Intensity of Pressure on the Bottom of the Tie When the Tie is Being Forced into the Ballast.—The friction between the tie and the ballast is probably less than the friction between the particles of the ballast, hence the ballast in contact with the bottom of the tie will be the first to move when the tie is heavily loaded. Consider a section of tie one unit long. Let the vertical unit-pressure at the edge be p_o, at the center be p_c, and at a distance x from the edge

be p. Let the coefficient of friction between the tie and the ballast be f, and the width of the tie be b. Let the total load on the tie be P and let l be the length of the tie. When motion is impending the intensity of pressure increases from the edge to the center of the tie because the intensity of vertical pressure at any point is limited by the available lateral pressure.

In Fig. 67 at (a), p_a is the resultant intensity of pressure at any point on the bottom of the tie when motion is impending. Expressed in terms of the vertical unit-pressure p at the point, the value of p_a is

$$p_a = \frac{p}{\cos.\ \theta}$$

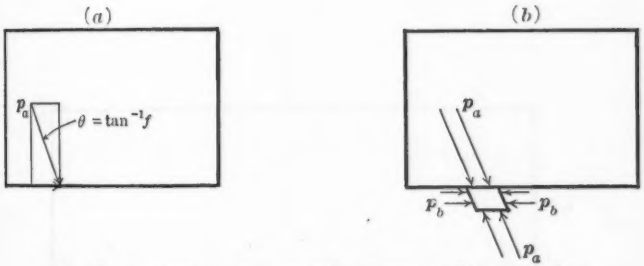

FIG. 67.—DIAGRAMS ILLUSTRATING PRESSURES ON BOTTOM OF TIE.

The horizontal pressure in the ballast at the point is the conjugate of the pressure p_a and may be found from Equation (16). For given values of θ and ϕ, using k as the resulting constant,

$$p_b = kp_a$$

in which

$$k = \frac{\cos.\ \theta - \sqrt{\cos.^2 \theta - \cos.^2 \phi}}{\cos.\ \theta + \sqrt{\cos.^2 \theta - \cos.^2 \phi}}$$

The total frictional force from the edge of the tie to a point x distant is equal to the horizontal thrust $\frac{k\,p}{\cos.\ \theta}$. In the distance dx, Fig. 68, the added friction amounts to $f\ p\ dx$, which can hold in equilibrium an additional horizontal thrust equal to

$$\frac{k\ dp}{\cos.\ \theta} = f\ p\ dx$$

Hence

$$\frac{k}{\cos.\,\theta}\int_{p_0}^{p}\frac{dp}{p} = f\int_0^x dx$$

Integrating,

$$\frac{k}{\cos.\,\theta}\log._e\frac{p}{p_0} = f\,x$$

$$\frac{p}{p_0} = e^{\frac{f\,x\cos.\,\theta}{k}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18)$$

where e is the Naperian base of logarithms. The vertical unit-pressure at the center is

$$p_c = p_0\,e^{\frac{f\,b\cos.\,\theta}{2\,k}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19)$$

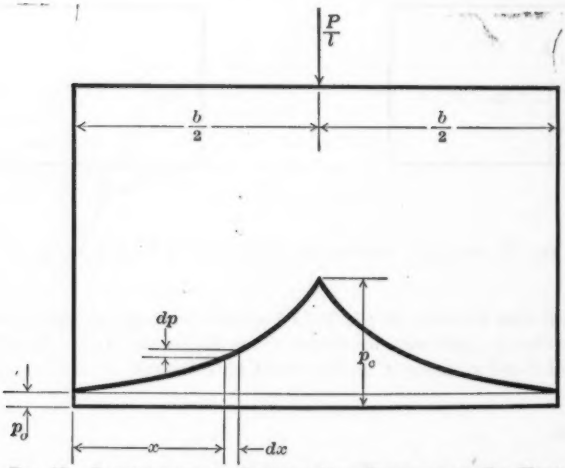

FIG. 68.—DISTRIBUTION OF VERTICAL UNIT-PRESSURE ON TIE WHEN CARRYING ULTIMATE LOAD.

The total load which can be carried by the section of the tie without its being forced into the ballast is equal to the area under the curve in Fig. 68.

$$\frac{P}{l} = \frac{2\,p_0\,k}{f\cos.\,\theta}\left(e^{\frac{f\,b\cos.\,\theta}{2\,k}} - 1\right) \qquad \ldots\ldots\ldots\ldots\ldots\ldots(20)$$

This equation gives the ultimate load, P, which the tie will support.

The average vertical unit-pressure carried by the tie is

$$\frac{1}{b}\cdot\frac{2\,p_0\,k}{f\cos.\,\theta}\left(e^{\frac{f\,b\cos.\,\theta}{2k}} - 1\right) \qquad \ldots\ldots\ldots\ldots\ldots\ldots(21)$$

The ratio of the vertical unit-pressure at the center to the average vertical unit-pressure on the tie is

$$\frac{p_c}{\frac{P}{b\,l}} = \frac{f\,b\cos.\,\theta\; e^{\frac{f\,b\cos.\,\theta}{2k}}}{2\,k\left(e^{\frac{f\,b\cos.\,\theta}{2k}} - 1\right)} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

In making numerical calculations it is best to change from the Naperian base to the base of common logarithms by means of the equation

$$e^{\frac{f\,b\cos.\,\theta}{2k}} = (10)^{\frac{f\,b\cos.\,\theta}{4.6k}}.$$

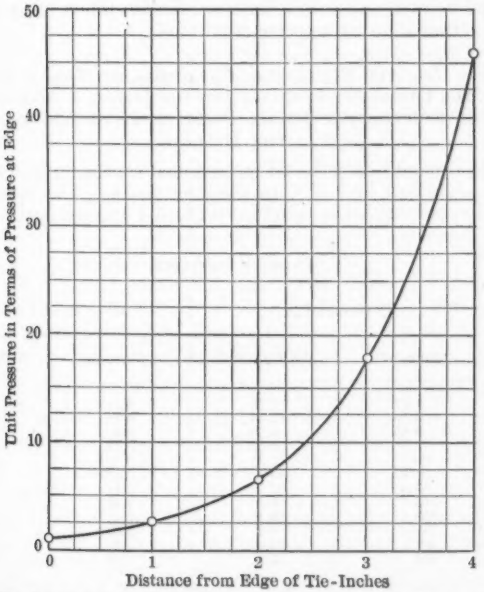

FIG. 69.—DIAGRAM SHOWING RELATIVE PRESSURES ON TIE WHEN CARRYING ULTIMATE LOAD FOR TAN. $\phi = 2/3$ AND TAN. $\theta = 0.4$

Values calculated from Equation (18) have been plotted in Fig. 69, which gives the greatest intensity of pressure that can exist at points away from the edge of the tie in terms of the intensity of pressure at the edge of the tie for assumed conditions of friction. It illustrates the rapid increase in intensity from the edge of the tie inward, which could be developed under the assumed conditions, when the tie is on the point of being forced into the ballast.

The ultimate supporting power of the tie is shown by Equation (20) to increase rapidly with the width. Using the assumptions here made, Table 18 gives the relative ultimate supporting capacity of ties of various widths, for tie on point of being forced into the ballast, based on an angle of repose of $1\frac{1}{2}$ to 1 and on a coefficient of friction between tie and ballast of 0.4. This is intended to represent approximately the conditions during quiescent loading. The relative ultimate supporting capacity of ties of various widths, for tie on point of being forced into the ballast, based on an angle of repose of 3 to 1 and on a coefficient of friction between tie and ballast of 0.2, is also given. This is thought to approximate the conditions when the application of load is accompanied by jarring as in the case of train loads. The exact values of the friction angles are not known. Table 18, of course, has an analytical, rather than an experimental basis.

TABLE 18.—Relative Supporting Capacities of Ties of Different Widths, for Quiescent Loadings and for Loadings Accompanied by Jarring, for Tie on Point of being Forced into the Ballast.

Quiescent load condition is based on assumed coefficient of 0.4 between tie and ballast and of $\frac{3}{1}$ between particles of the ballast. For jarring loads values of 0.2 and $\frac{1}{3}$ are assumed.

Width of tie, inches.	Ultimate Supporting Capacity.			
	In terms of p_0.		In terms of 8-in. tie.	
	Quiescent.	With jarring.	Quiescent.	With jarring.
1	1.27	1.08	0.01	0.07
2	3.33	2.34	0.04	0.15
3	6.65	3.79	0.07	0.24

12	650	35.2	8.94	2.20

Except when heavy loads are carried on loose ballast, the distribution of pressure on a railroad tie is not in general that shown in Fig. 69, because the tie is not at the point of being forced into the ballast. After the track has been in service for a time the ballast beneath the tie will become compacted. The carrying capacity of the ballast at the edge of the tie will then have been increased, and since the ultimate carrying capacity of the tie varies directly with the carrying capacity of the ballast at the edge of the tie, the ultimate carrying

capacity will also have been increased over what it could carry when the ballast was first placed.

At (*a*) in Fig. 70 is shown the distribution of pressure on the bottom of the tie when it is carrying its ultimate load. Vectors giving the directions and relative magnitudes of the unit-pressures are shown. The ordinates of the full line curve represent the vertical components of these pressures. When the tie is on the point of being forced into the ballast, the angle which the pressure makes with the normal to the bottom of the tie is the angle of friction between tie and ballast. The ultimate vertical unit-pressure which may be developed on the bottom of the tie after the ballast has become compacted is indicated by the dotted curve at (*b*) in Fig. 70. The distribution and direction of pressure on the tie under ordinary loadings (that is, loadings less than the ultimate load which the ballast can carry) will be somewhat as shown by the full line curve and the vectors. It is seen that the distribution shown is different from that at ultimate load.

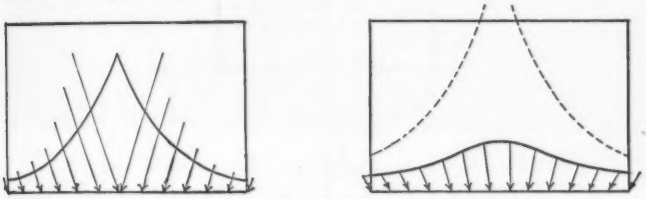

FIG. 70.—DIAGRAM SHOWING RELATIVE DIRECTIONS AND MAGNITUDES OF PRESSURES ON TIE UNDER ULTIMATE LOAD AND UNDER ORDINARY LOADS.

The coefficient of friction between the tie and ballast and between parts of the ballast will be much less under the jarring and pounding action of train loads than under loads applied without shock or vibration. The ballast gradually works from under the tie and in time the track must be retamped. From the discussion it is evident that in tamping it is not enough to force ballast beneath the tie unless the ballast at the edge of the tie is compacted, otherwise the track will settle rapidly. Especial attention therefore should be given to methods of tamping which insure a compacted ballast at the edge of the tie.

35.—Method for Finding the Distribution of Pressure in Ballast Beneath a Cross-Tie.—It has been shown that the pressure in ballast against the tie is greater near the center than at the edge of the tie and that because of the friction between tie and ballast the pressures are not perpendicular to the bottom of the tie. It has also been shown that the distribution of pressure in granular material when a narrow strip is loaded may be represented by an expression of the type of the probability equation, or by lines of pressure. By dividing the bottom surface

of the tie into narrow strips and using the average load on each strip and taking its direction into account, the total intensity of pressure at any point in the ballast may be found by adding the pressures at that point due to the loads on the several strips.

In order to use Equation (15) to find the vertical pressure at any point B in the ballast due to a pressure p_a at A, Fig. 71, when p_a is not vertical, it is necessary to determine the distances x_1 and h_1, and use them for x and h in Equation (15). It may be shown from the geometrical relations that

$$x_1 = (h \tan. \theta - a + x) \cos. \theta \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

$$h_1 = \frac{h - x_1 \sin. \theta}{\cos. \theta} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

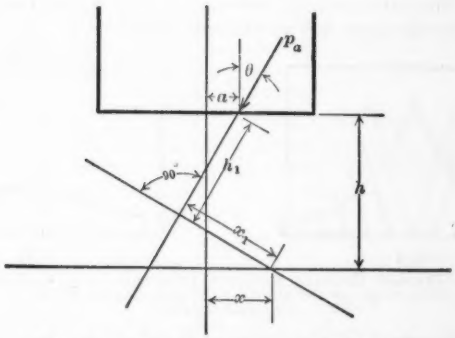

FIG. 71.—DIAGRAM FOR DETERMINING x_1 AND h_1.

The pressure p found from Equation (15) is in the direction of the pressure p_a. The vertical component of the pressure is found by multiplying the pressure found by cos. θ.

The pressure p_a at any point on the bottom of the tie probably should be taken as the greatest principal pressure at the point. The greatest principal pressure will make a greater angle with the vertical than does the conjugate pressure and its magnitude is greater. However, due to the uncertainties in the magnitude and direction of the pressures on a tie, it is a needless refinement to take account of the principal pressures, and values of the conjugate pressures will be used instead.

B.—Experimental Work in Laboratory.

36.—Earlier Experiments at the University of Illinois.—Experimental work on the transmission of vertical pressure through granular material was carried on for a number of years at the University of

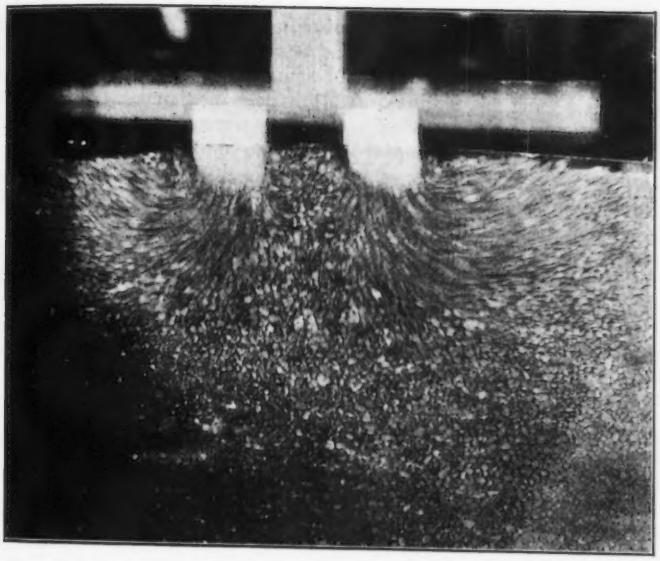

FIG. 72.—LINES OF MOVEMENT OF SAND BALLAST UNDER LOAD.

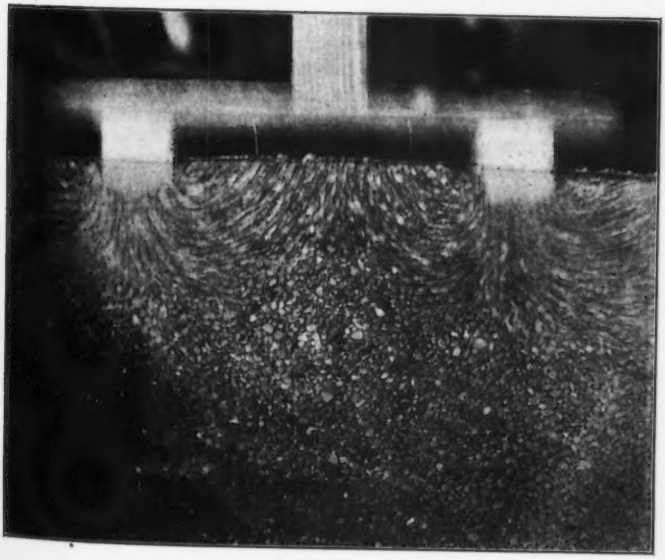

FIG. 73.—LINES OF MOVEMENT OF SAND BALLAST UNDER LOAD.

Illinois in connection with undergraduate thesis work.* Although the experiments were limited to circular bearing areas and therefore are not directly applicable to railroad track, the work proved very instructive and the experience gained was helpful in planning the more elaborate experimental work afterward undertaken for the Joint Committee.

Figs. 72 and 73 are from photographs taken by Messrs. L. N. Fisher and H. F. Wagner in 1912 and included in their thesis. The photographs were made by taking a time exposure of coarse sand behind a plate of glass while a load was being applied to two small blocks (2 by 2 in.). The images of the moving grains are elongated in the direction of motion, giving the appearance of lines of force in a magnetic field. The photographs indicate the paths of flow in the case of the very loose ballast used and, in a general way, indicate the tendencies of ballast movements in track under the action of load.

37.—The Laboratory Experimental Work.—The laboratory experimental work undertaken by the Committee was made in the Laboratory of Applied Mechanics of the University of Illinois. In the attempts which had been made to measure pressures in ballast under regular track conditions, difficulties were met that showed the advisability of conducting experiments in the laboratory where conditions could be controlled and results obtained to establish some of the basic principles of the action of ballast.

Two elevations showing the arrangement of the apparatus used in making the tests are shown in Fig. 74. A reinforced concrete slab 16 by 19 ft. and 12 in. deep supported the ballast. The load was applied to the ties by means of a jack whose upward thrust was carried by I-beams to four 1¼-in. steel rods having ends embedded in the concrete slab. The load applied by the jack was distributed to the one, two, or three ties used in the experiments by means of a system of levers. It was possible to divide the load among the ties in any manner desired. The load applied by the jack was measured by a calibrated steel spring. The arrangement of the apparatus can be seen in Fig. 75.

For measuring the intensity of pressure transmitted to various parts of the ballast, the pressure capsule shown in Fig. 76 was used. The following description which was given in the first progress report is here repeated for the convenience of the reader:

The elastic deflection of a thin steel diaphragm is used to measure the amount of pressure applied to the capsule. The pressure to be measured is received on the bearing plate *P*, which has an area of 5 sq. in.; the pressure is transmitted to the thin steel diaphragm *D*, which is fastened by screws around its circumference to the cast-

* An article by Prof. M. L. Enger describing the methods of experimenting and giving the results was published in the following papers: *Engineering Record*, Vol. 73, p. 106, January 22d, 1916; *Railway Age Gazette*, Vol. 60, p. 321, February 18th, 1916; *Engineering and Contracting*, Vol. XLV, p. 53, January 19th, 1916; and *Railway Review*, Vol. 58, p. 129, January 22d, 1916.

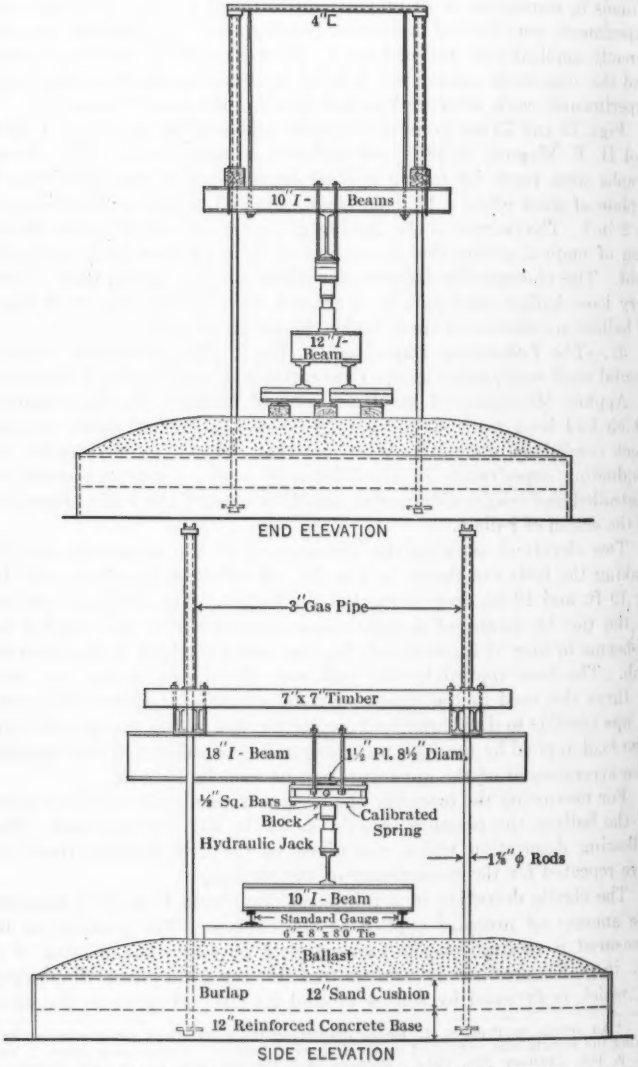

FIG. 74.—APPARATUS USED IN TESTS ON TRANSMISSION OF PRESSURE THROUGH BALLAST.

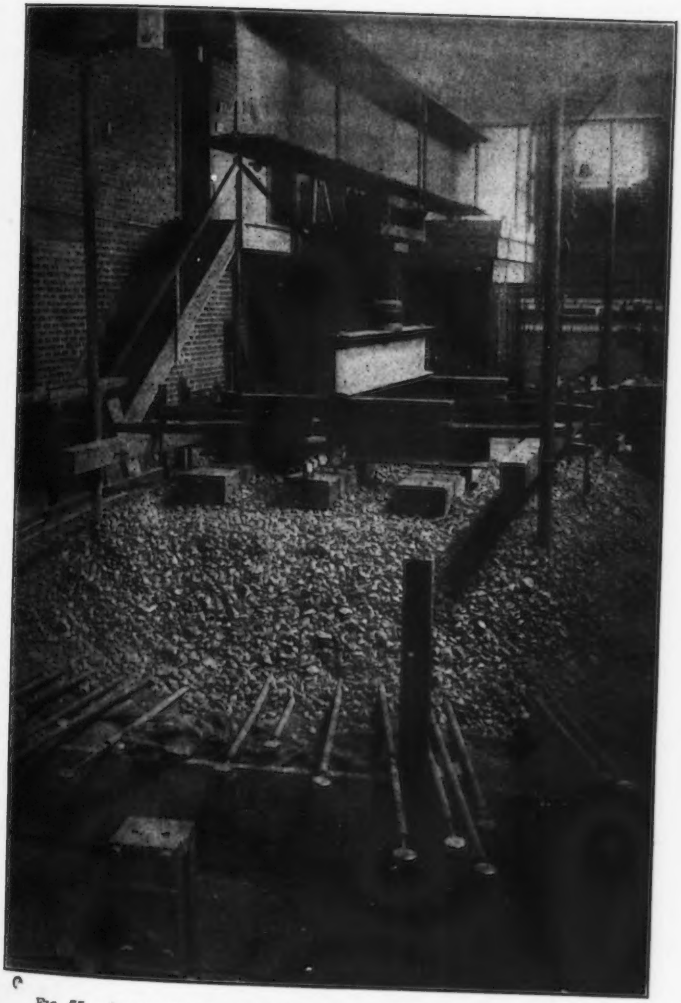

FIG. 75.—APPARATUS USED IN TESTS ON TRANSMISSION OF PRESSURE THROUGH BALLAST.

iron case B. The screw S which fastens the plate P to the diaphragm D is hardened and bears on one knife edge of the small bell-crank lever L which is pivoted at Q. The vertical deflection of the center of the diaphragm is transmitted by the bell-crank lever (magnified about three times) in a horizontal direction to the rod R which slides in guides NN' and is enclosed in a horizontal tube K and finally bears against plunger T of an indicating dial micrometer, whose movement

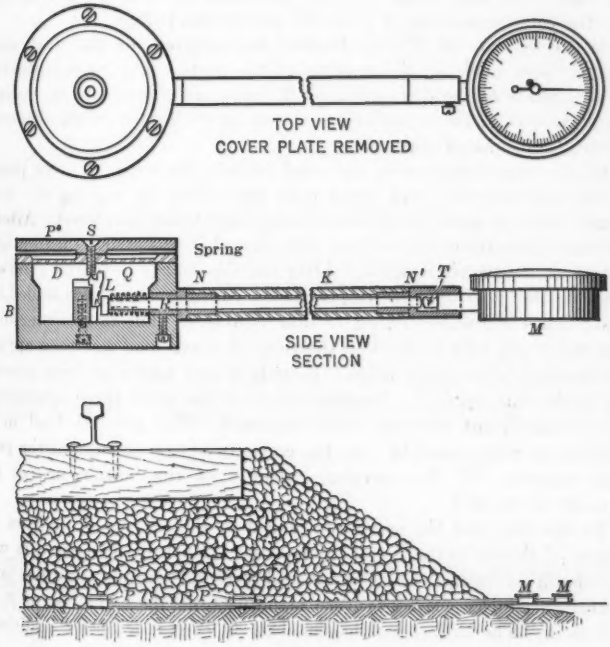

FIG. 76.—PRESSURE CAPSULE AND ITS PLACE IN BALLAST.

is thus a measure of the elastic deflection of the diaphragm D. If the material of the diaphragm is not stressed beyond its elastic limit the deflection of the diaphragm, and the consequent movement of the pointer of the dial micrometer, may be used to measure the load on the plate P. Sand and dirt are prevented from coming between the bearing plate P and the diaphragm by friction tape wrapped around the case of the pressure capsule. Each pressure capsule was calibrated after being taped, by placing it on a platform scale and by means of a screw clamp applying a series of loads covering the range of its use.

The thin elastic diaphragm is made of hardened steel. The bearing plate serves to take load of any distribution or concentration upon it and to apply this load as a concentrated load at the center of the diaphragm.

There was at first some difficulty due to ballast movements causing the tube to be pulled out of the capsule. Even after making a threaded connection between the tube and capsule there was some trouble from this cause. It was finally entirely overcome by slipping a 1-in. pipe over the tube, protecting it from the pull of the ballast.

38.—Procedure of Tests.—During the progress of the work some changes were made in the making of the tests. The most important changes relate to the disposition of the pressure capsules in the ballast. The locations of the capsules are shown in each case in the diagrams giving the results of the tests.

In the experiments with the sand ballast, the capsules were placed on the concrete slab and great care was taken in placing the sand around them in order to prevent them from being displaced. After a sufficient quantity of ballast had been placed it was struck off to a level surface at the required depth. After the ties had been placed carefully in the desired position with respect to the capsules, they were loaded five or six times before beginning to take readings. The micrometer dials were then read with no load on the ties. A small load was then applied and readings were again taken. Usually a zero load and three increasing loads were applied. Readings were taken until three consecutive sets of consistent readings were obtained. The greatest load to be applied was determined by: (*a*) the capacity of one or more of the pressure capsules, (*b*) the carrying capacity of the ballast, or (*c*) the capacity of the jack.

In the first test the sand was placed so that it was 6 in. from the bottom of the tie to the top of the capsule. When the experiments with this depth of ballast had been completed the pressure capsules were rearranged and experiments were made with depths of ballast of 9, 18, and 25 in. The ballast was loosened up in each case before additional sand was put on.

Following these tests, the ballast was removed. The capsules were recalibrated and given a different arrangement (see Fig. 77) and were covered with sand ballast to a depth of 12 in. from bottom of tie to top of capsule.

Depths of broken stone ballast of 12 in. and 18 in. were next used. In these experiments a 15-in. sand cushion was placed on the concrete slab and covered with burlap. The capsules were placed on the burlap as shown in Fig. 78. Then the broken stone was carefully placed so as not to disturb the capsules. The experiments were made in the same manner as with sand ballast.

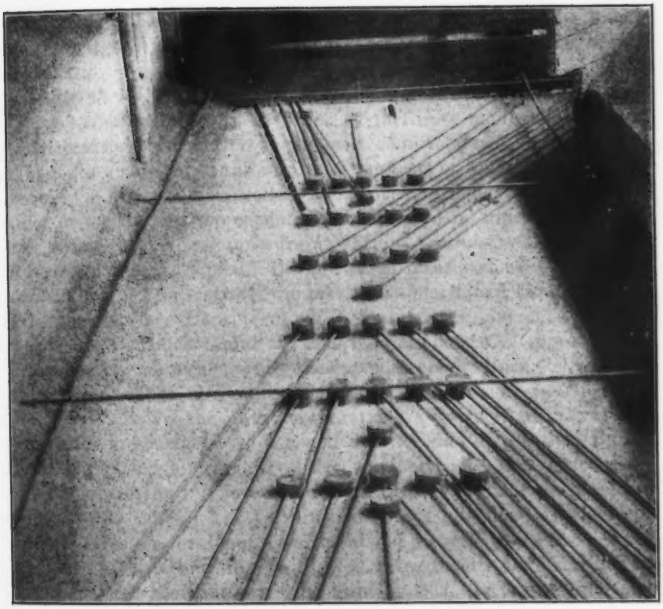

FIG. 77.—ARRANGEMENT OF CAPSULES AND RODS UNDER SAND BALLAST.

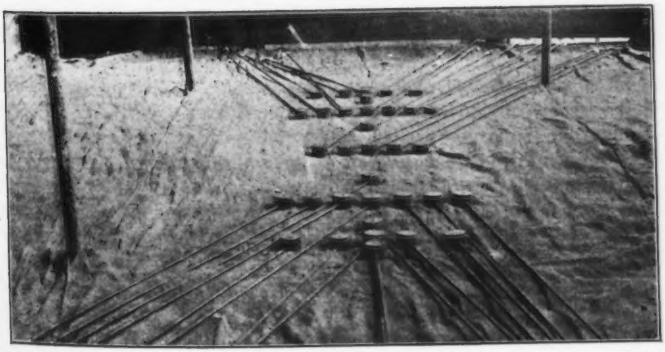

FIG. 78.—ARRANGEMENT OF CAPSULES FOR TESTS WITH BROKEN STONE BALLAST.

Pebble ballast having a depth of 12 in. from tie to capsule was next used. The capsules were recalibrated and were placed on the burlap with a slightly different arrangement than was used in the broken stone ballast.

39.—Results of Tests.—The results of the tests are given in Figs. 79 to 87, presented graphically in order to facilitate comparison and to give the essential information in the most compact form. For example, in Fig. 80, there are given the results of the tests on the transmission of pressure from a single tie through 12 in. of sand ballast. The relative position of the tie and the capsule is shown, and in addition there are curves giving the vertical pressure at various sections. The curves at *AB* represent the averages of the pressures measured by the capsules at *AB* and *LM*. To illustrate, the pressures determined from the readings of the Pressure Capsules 1, 2, 3, and 4, were averaged and are plotted above Capsules 1 and 2. The curves above *CD* represent the average pressures as measured by the capsules on the lines *CD* and *JK*, and the curves above *GH* represent the average pressure measured on *EF* and *GH*. Below the plan view of the tie are plotted curves representing the pressures 12 in. below the center line of the tie. By the manner of plotting all the curves are symmetrical. The dotted lines in Fig. 80 represent the intensity of pressure when the tie carries a total load of 35 000 lb. The full lines are for a total load of 24 000 lb.

Fig. 79 gives the results of experiments on a single tie with depths of sand ballast of 6, 9, and 18 in., Fig. 80 gives results for sand ballast 12 in. deep when the ordinary 6 by 8-in. by 8-ft. tie is used and also when a tie with a wedge-shaped bottom is used. The wedge was 1½ in. high in the middle of the tie. It will be noted that the pressure is somewhat more widely distributed with the wedge-shaped tie.

Figs. 81, 82, and 83 give the results of the experiments for depths of sand ballast of 9, 18, and 25 in. when the ties are equally loaded and when the middle tie carries twice the load carried by either of the outside ties.

Fig. 84 gives the results of the experiments for 12 in. of broken stone ballast and for the same depth of pebble ballast. The broken stone used was the standard limestone ballast material furnished by the Illinois Central Railroad. The pebble ballast consisted of pebbles ranging in size from about ¼ in. to 1½ in. and was free from sand. It will be noted that the results of experiments with rock ballast are more erratic than with pebbles or with sand. This was to be expected because a short chain of the large grains may bring a heavy pressure on a capsule, or it may miss it entirely. When average pressures are taken there is a surprising similarity in the distribution of pressure through sand, pebble, and broken stone ballast.

Fig. 85 shows the distribution of pressure through 12 in. of broken stone when the load is carried on a 6 by 10-in. by 8-ft. tie with the 10-

Fig. 86 shows the distribution of pressure through 18 in. of broken stone ballast when three loaded ties are used and also when all the load is carried on one tie.

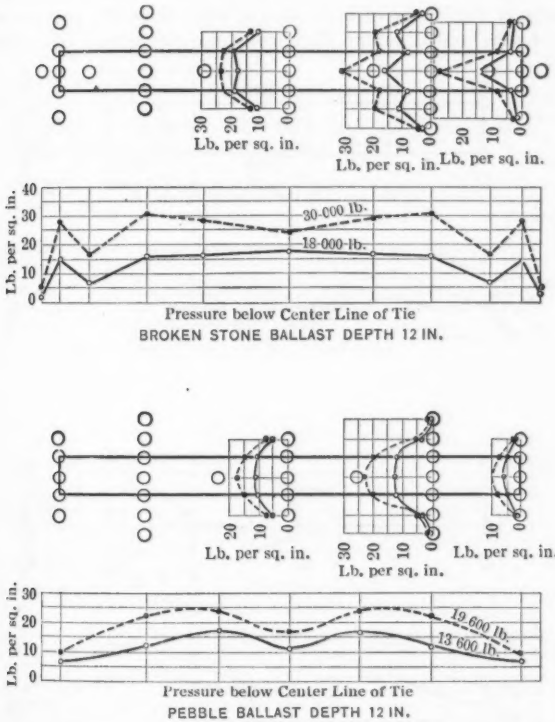

FIG. 84.—DISTRIBUTION OF PRESSURE AT A DEPTH OF 12 IN. OF BROKEN STONE AND 12 IN. OF PEBBLE BALLAST BELOW A SINGLE TIE.

Fig. 87 shows the distribution of pressure on the bottom of a tie which rests on pebble ballast, and also the pressure measured simultaneously at a depth of 12 in. below the tie. The tie was prepared by embedding the capsules in the tie. The circular bearing plate of the capsule had been replaced with rectangular bearing plates, 3 by 1 in., and the surface of these was left flush with the bottom of the tie. The positions of the pressure capsules in the tie are indicated in the diagram.

C.—Discussion of Results of Tests.

40.—Diagrams of Average Pressure and Use of Superposition of Pressures.—In order to eliminate the variations in pressure due to flexibility of tie and other causes, for the study of the data, the pressures measured by all capsules located at the same distance from the longitudinal axis of the tie have been averaged. Using this method the diagrams in Fig. 88 have been drawn; they show the pressure at different depths and different distances from the center line of the tie

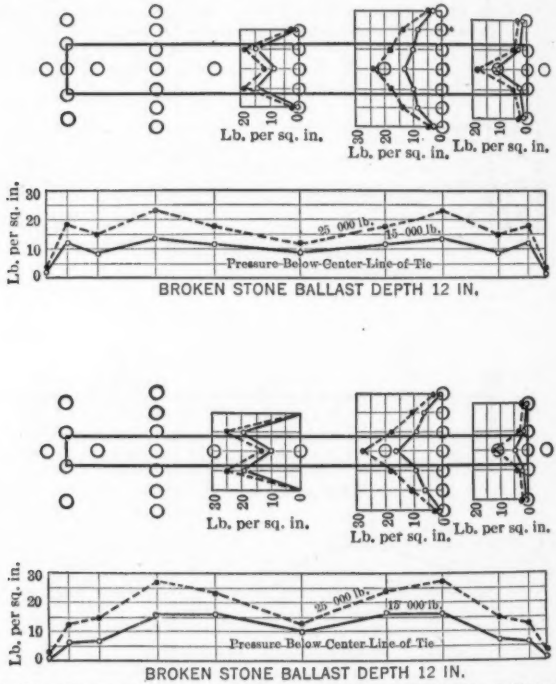

FIG. 85.—DISTRIBUTION OF PRESSURE AT A DEPTH OF 12 IN. OF BROKEN STONE BALLAST BELOW A TIE 10 IN. WIDE AND BELOW ONE 6 IN. WIDE.

when a single tie is loaded, as given by the averages of the readings. The pressure is expressed as a percentage of the average intensity of pressure over the tie. The average result for the three loads has been used. In addition, the highest and the lowest pressure measured by any capsule is shown. Using the same method, the results obtained in tests with three ties have been plotted by full lines in Figs. 89 to 93. There have also been plotted the dotted lines marked "superposed pressure curve".

This method of superposition considers that at a given point the combined effect of several ties is the sum of the effects of the individual ties. The effect of a tie at a given point was obtained from the curves of Fig. 88. It will be noted that the superposed pressure curves agree

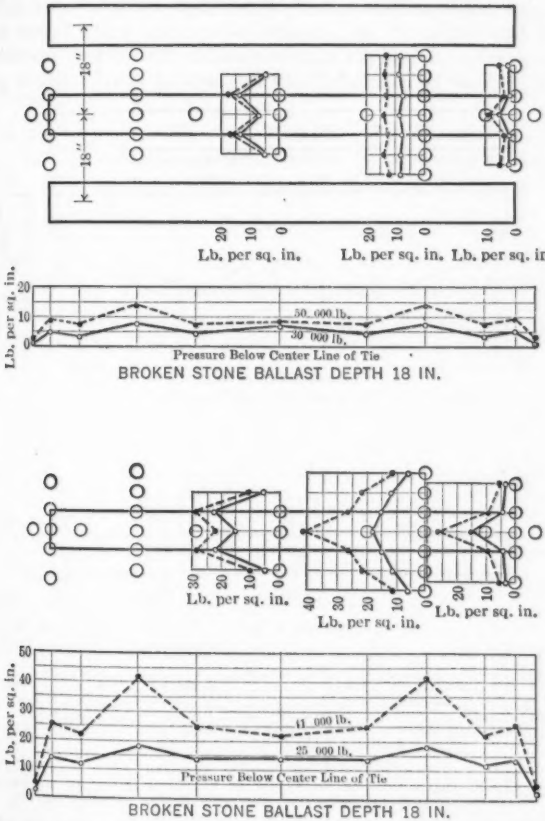

FIG. 86.—DISTRIBUTION OF PRESSURE AT A DEPTH OF 18 IN. OF BROKEN STONE BALLAST BELOW THREE TIES AND BELOW A SINGLE TIE.

with the experimental curves reasonably well, indicating that the vertical pressure at any given point in the ballast is the sum of the vertical pressures which would be caused at that point by adding the pressures from the ties considered separately. By means of this principle, which seems to be established by these experiments, the results

of the experiments with a single tie may be used to determine the pressure in ballast under any condition of the spacing and loading.

41.—Comparison of Pressure Distributions in Different Kinds of Ballast.—An examination of the pressure curves for the sand, broken stone, and pebble ballasts will show that there are no decided differences in the distribution of the pressure at a given depth except that the results found with sand are more concordant than those with the coarser ballast. It may be concluded that the laws of distribution of pressure

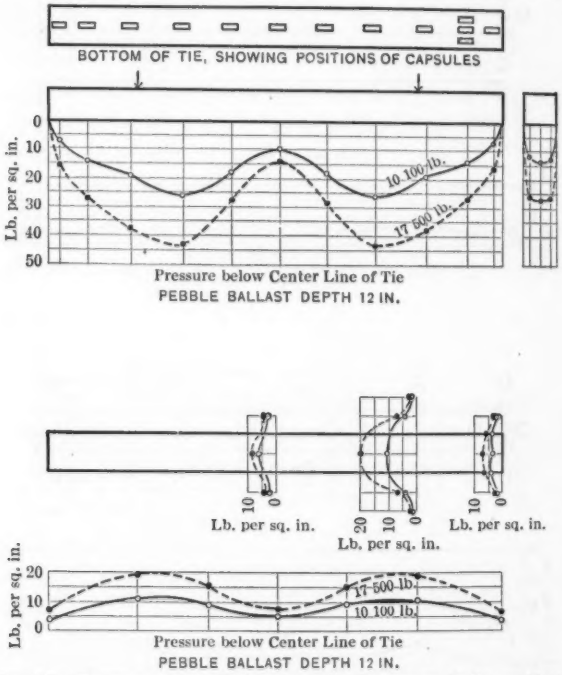

FIG. 87.—DISTRIBUTION OF PRESSURE AT A DEPTH OF 12 IN. OF PEBBLE BALLAST BELOW A SINGLE TIE AND AT THE BOTTOM OF THE TIE.

through ballast (non-cohesive granular material) are practically the same for the various kinds of ballast.

It should be borne in mind that the foregoing statement applies to distribution of pressure only; ultimate bearing load, action under vibration, and other properties of ballast will differ materially.

42.—Intensity of Pressure at Different Depths Below Center Line of Tie.—The intensity of pressure below the center line of the tie at various depths has been given in Fig. 88. Using values taken from this

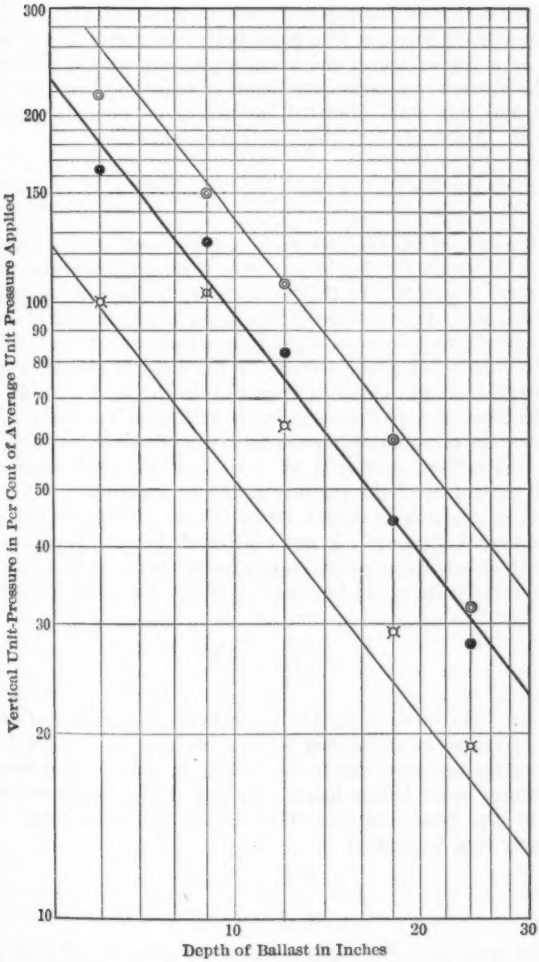

FIG. 94.—RELATION OF INTENSITY OF PRESSURE UNDER CENTER LINE OF TIE TO DEPTH BELOW BOTTOM OF TIE. LOGARITHMIC SCALE.

diagram, Fig. 94 has been drawn to express by logarithmic co-ordinates the relation between the unit-pressure at points below the center line of tie and the corresponding depth of ballast. The ordinate of a plotted point represents the pressure at a point below the center line of the tie expressed as a percentage of the average pressure over the bottom of the tie; the abscissa represents the depth of ballast at the point. The maximum and minimum observed intensities of pressure have also been plotted. A straight line the equation of which is

$$p_c = \frac{16.8\ p_a}{h^{1.25}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

has been drawn and fits the observations fairly well within the range of the tests, although for depths less than 4 in. and more than 30 in. the results are too high. In this equation p_a is the average pressure over the tie and p_c the pressure at the given point directly below the center line of tie, both in pounds per square inch, and h is the vertical distance in inches below the bottom of the tie. It should be noted that this expression was obtained from tests with ties 8 in. wide.

43.—Distribution of Pressure Over a Horizontal Plane.—It is desired to obtain an equation for the intensity of pressure at any point (x, h) in the ballast, developed by a tie carrying load, which shall agree with the values of the pressure found by experiment.

From the discussion in Article 30 on "Paths of Pressure and Laws of Distribution of Pressure", it was concluded that the distribution of the intensity of vertical pressure on any horizontal plane due to a load p_a on a narrow strip would be represented by Equation (15) of the form

$$p = \frac{k\ p_a}{\sqrt{\pi}}\ e^{-k^2x^2}.$$

Since a tie may be considered to be made up of a number of narrow strips, the pressure in the ballast below a tie may be considered as a composite of the pressures due to the strips. It is found that the composite pressures in the ballast below a tie may also be represented by an equation of the form Equation (15) except at small depths. The equation may then be written

$$p = \frac{K\ P_a}{\sqrt{\pi}}\ e^{-K^2x^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

p being the intensity of vertical pressure on a horizontal plane at a distance x from the vertical center line of the tie due to a load p_a per inch of length of tie. For an 8-in. tie

$$P_a = 8\ p_a$$

in which p_a is the average pressure on bottom of tie in pounds per square inch. Hence,

$$p = \frac{8 K p_a}{\sqrt{\pi}} e^{-K^2 x^2}$$

When $x = 0$

$$p = p_c = \frac{8 K p_a}{\sqrt{\pi}}$$

In Article 42 it was found from the results of experiments with 8-in. ties in Equation (25) that

$$p_c = \frac{16.8\, p_a}{h^{1.25}}$$

Equating the values of p_c and solving for K:

$$K = \frac{2.1 \sqrt{\pi}}{h^{1.25}}$$

Substituting this value of K in the equation and changing from the base e to the base 10, the following empirical equation for p is obtained:

$$p = \frac{16.8\, p_a}{h^{1.25}} (10)^{-6.05 \frac{x^2}{h^{2.5}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

in which p_a is the average intensity of pressure over the tie per square inch, and p is the pressure per square inch at a point on a horizontal plane h in. below the tie and x in. from the center line of the tie. The equation applies only to an 8-in. tie and is applicable for depths from about 4 in. to about 30 in.

The dotted lines in Fig. 88 represent the pressures as determined by Equation (27). It will be seen that the agreement between the experiments and the equation is fairly good.

44.—Contours of Equal Vertical Unit-Pressure.—From the results of the tests it is possible to draw the contours of equal vertical unit-pressure beneath one or more loaded railroad ties. Fig. 95 shows the contours of pressure beneath a single 6 by 8-in. by 8-ft. tie. The contours are designated by percentages of the average pressure applied to the ballast by the tie. In Figs. 96, 97, and 98, contours of equal vertical pressure are shown beneath a series of equally loaded ties for three different tie spacings. It will be noted that in general the vertical pressures become nearly constant at a depth equal to the tie spacing. It should be added that in determining the contours the principle of superposition and the laws of distribution of pressure given by the equations already derived have been used. These laws may be applied to conditions not covered by the experimental work.

45.—Lines of Pressure.—In Article 30 on "Paths of Pressure and Law of Distribution of Pressure", it was concluded that a pressure p_a per unit length applied to a long, narrow strip will develop an intensity

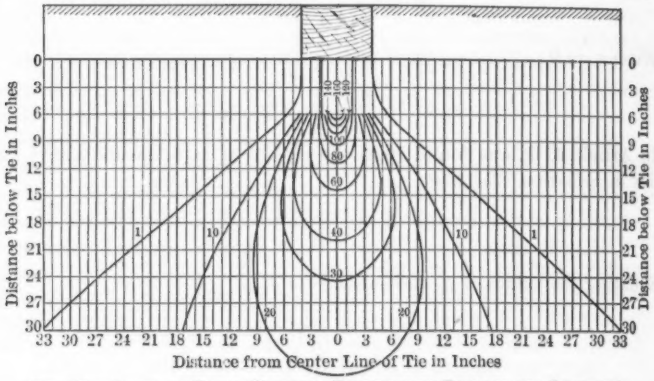

FIG. 95.—LINES OF EQUAL VERTICAL PRESSURE IN BALLAST FOR LOAD ON A SINGLE TIE.

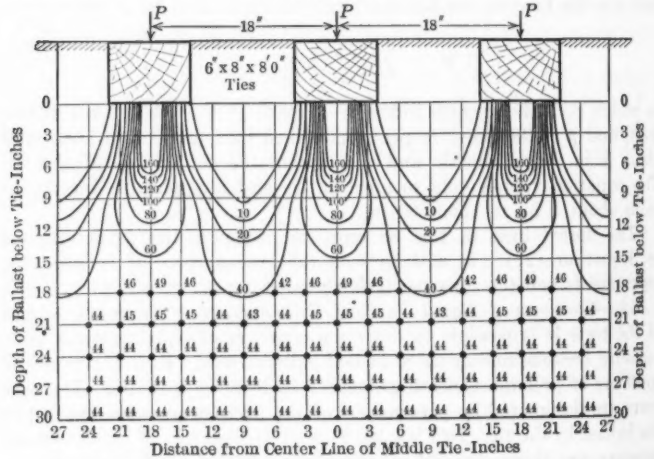

FIG. 96.—LINES OF EQUAL VERTICAL PRESSURE IN BALLAST FOR EQUAL LOADS ON TIES. SPACING 18 IN., CENTER TO CENTER.

of pressure p on a horizontal plane a distance h below the loaded strip and at a distance x from the line of action of the applied load p_a, in accordance with Equation (15) as follows:

$$p = \frac{k\,p_a}{\sqrt{\pi}}\,e^{-k^2x^2}.$$

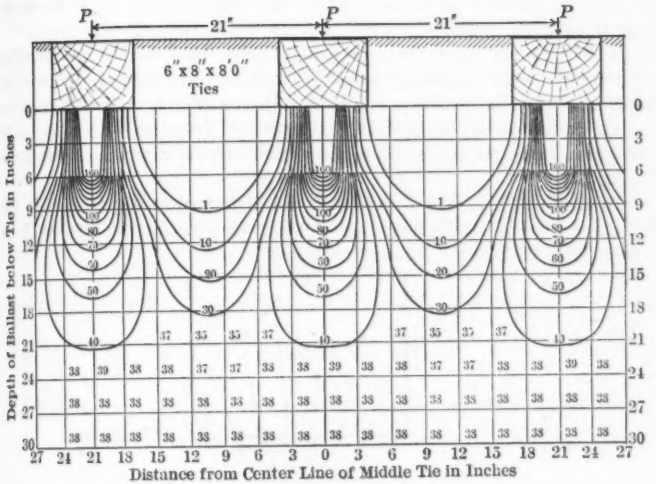

FIG. 97.—LINES OF EQUAL VERTICAL PRESSURE IN BALLAST FOR EQUAL LOADS ON TIES. SPACING 21 IN., CENTER TO CENTER.

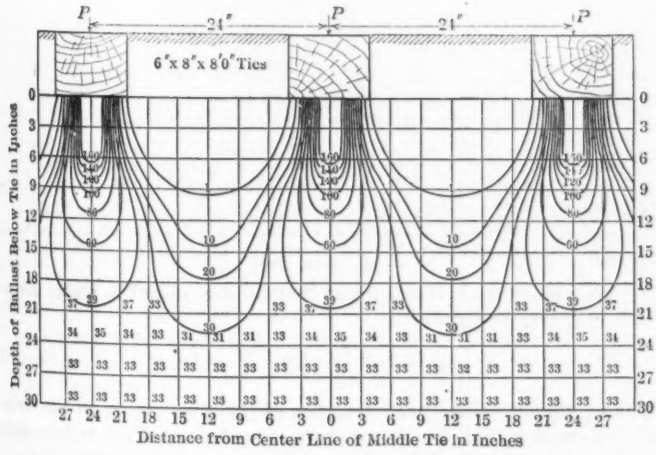

FIG. 98.—LINES OF EQUAL VERTICAL PRESSURE IN BALLAST FOR EQUAL LOADS ON TIES. SPACING 24 IN., CENTER TO CENTER.

In this equation k is a function of the depth h and must be determined by experiment.

The bottom of the tie may be considered to be divided into a number of narrow strips carrying loads of varying intensity and direction, each producing pressures in the ballast in accordance with the equation. At any point in the ballast the intensity of pressure will be equal to the sum of the pressures from the various strips into which the tie is divided.

In Article 31 it was shown that the distribution of pressure in the ballast due to a load on a narrow strip may be represented by lines which were designated lines of pressure.

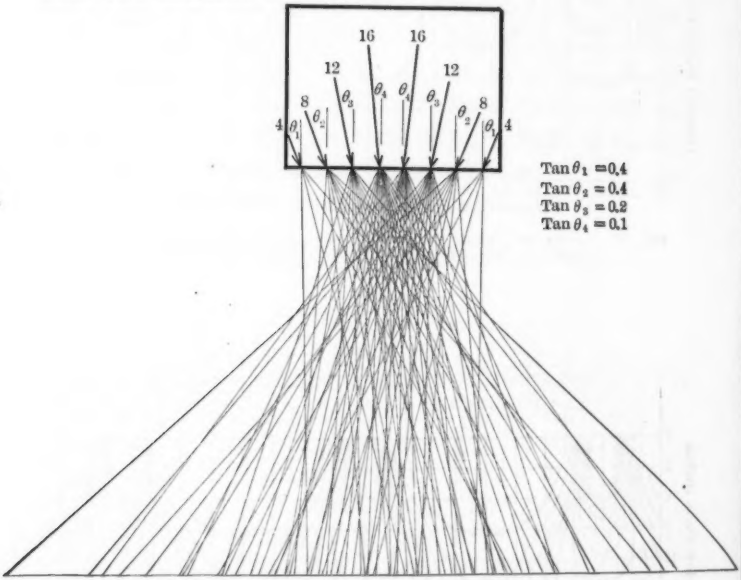

FIG. 99.—DIAGRAMMATIC REPRESENTATION OF LINES OF PRESSURE FOR A TIE 8 IN. WIDE.

After many trials it was found that for dimensions in inches Equation (15) may be written

$$p = 1.23 \frac{p_a}{h} (10)^{-2.06 \left(\frac{x}{h}\right)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

Taking the directions and intensities of the pressures p_a on the strips as indicated in Fig. 99, the pressures thus found in the ballast agree quite closely with the values determined in the experiments.

The lines of pressure determined from Equation (28) are straight lines, and were laid out in the following manner: The distribution of

pressure at a depth of 24 in. for the given value of p_a on a given strip was calculated by Equation (28). The results were then plotted on cross-section paper to a large scale using unit-pressures as ordinates and distances from the line of action of the applied pressure as abscissas. The area under the curve was divided into parts each representing 1 lb. and the abscissas of the centroids of such areas were determined. In making the desired division of the area it was found convenient to plot a mass curve beginning at the center line. From the center of the given strip on the tie, a line was drawn in the direction of the applied pressure p_a and a perpendicular line was drawn at a distance representing 24 in. Upon this perpendicular the abscissas determined previously were plotted. Straight lines through these points and the middle of the strip therefore represent lines of pressure of 1 lb. each. The number of such lines passing through a width of 1 in. on a horizontal plane represents the intensity of pressure.

TABLE 19.—CALCULATED AND EXPERIMENTAL VALUES OF UNIT-PRESSURE AT VARIOUS POINTS BELOW A SINGLE TIE. AVERAGE LOAD ON TIE, 100 LB. PER SQ. IN.

h	x	Calculated p	Experimental p
6	0	161	163
9	0	106	126
12	0	75	83
12	4	47	50
12	8	12	16
18	0	50	45
18	6	30	34
18	10	15	16
18	15	5	4
24	0	37	31
24	10	18	17

Figs. 99 and 100 were plotted in the manner described, Fig. 99 representing the 1-lb. lines of pressure when the average load on the tie is 10 lb. per sq. in. and Fig. 100 when the average load is 100 lb. per sq. in., the only difference being that there are ten times as many lines in the last case. At any point in the ballast the number of lines in 1 in. of width will then represent the number of pounds of pressure per square inch at that point. As a line may represent any intensity of pressure (pounds being only as an illustration), both figures may be considered to represent the relative distribution of pressure for any given load on the tie.

The vertical unit-pressure at any point may be determined with greater accuracy by substituting for x and h in Equation (28) the values of x_1 and h_1, found by means of Equations (23) and (24) for each unit strip on the tie, and adding the results. The results

of some such calculations are given in Table 19, a width of tie of 8 in. being used, and experimental results are given for comparison.

It will be seen that the distribution of pressure found in the experiments may be accounted for by the superposition of pressures of differing intensities and inclinations over the bottom of the tie.

The method of lines of pressure, in conjunction with the variation of pressure beneath the tie, supplies explanations of the concentration and distribution of pressure in the ballast.

46.—General Discussion.—The following observations summarize some of the results of the tests and analysis and bring out in part the phenomena attending the transmission of pressure from the tie through the ballast.

The bearing pressure of the tie varies in intensity from its edge to its middle line; the maximum intensity is dependent upon the intensity of pressure developed at the edge. A variation in intensity exists also along the length of the tie.

The pressures which react from the lower face of the tie act in other than vertical lines, the greatest variation from the vertical direction being at the edge of the tie.

There is a concentration of pressure a short distance below the tie, say, at 3 to 4 in., and the intensity of pressure in the ballast at such a depth is greater than that which exists at the bottom of the tie.

For the tie of ordinary width the intensity of pressure at a depth of 6 in. and the distribution of vertical pressure over a horizontal plane at this depth do not differ greatly from those existing immediately under the tie. The directions of the pressures are not the same. At or below this depth the distribution of pressure laterally begins, with a consequent decrease in maximum intensity of pressure, and the change becomes more apparent as the depth increases.

The foregoing relates to the transmission of pressure from a single tie. For a number of ties with the ordinary tie spacing, the effect of the combination of pressures transmitted is readily found by superposing the values of the pressures from the several ties as obtained for a plane at the same depth. For the ordinary width of tie, the effect of the pressure transmitted from the adjacent tie to points midway between ties (overlapping lines of pressure) is noticeable at a depth equal to about half of the usual tie spacing. At a depth of three-fourths of the ordinary tie spacing the pressure immediately under the center of the tie is about one and one-half times that resulting from a uniform distribution over the horizontal plane. At a depth equal to the ordinary tie spacing the lateral distribution has become such that the variation in intensity of pressure from tie to tie is small.

The variation in intensity of pressure in the ballast lengthwise of the tie (which is dependent upon size and stiffness of tie, quality of tamping, and condition of the bed on which the tie rests) becomes

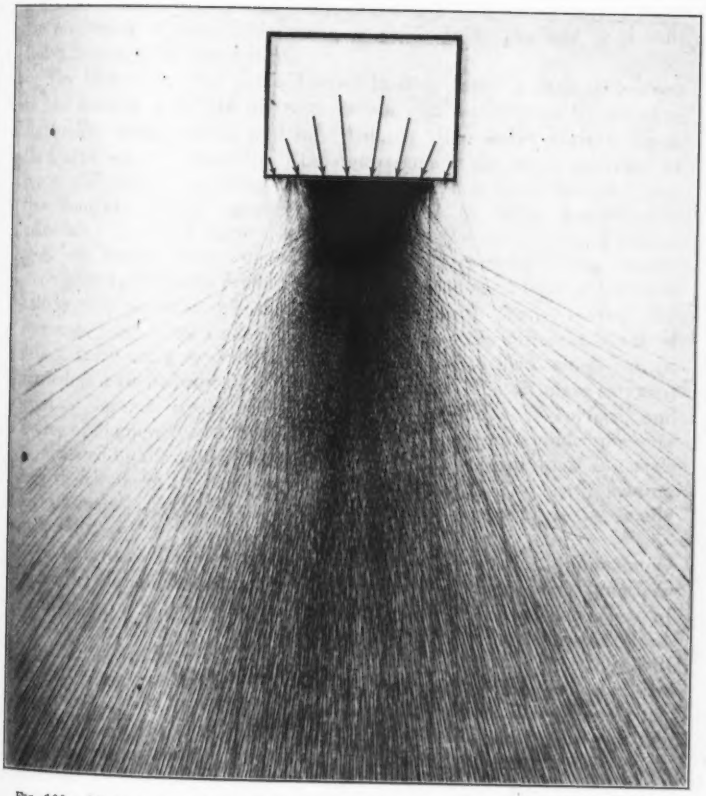

FIG. 100.—DIAGRAMMATIC REPRESENTATION OF LINES OF PRESSURE FOR A TIE 8 IN. WIDE, USING TEN TIMES AS MANY LINES AS ARE GIVEN IN FIG. 99.

less and less with increase in depth, and it may be expected that the variations will be smoothed out at a depth equal to the ordinary tie spacing, or a few inches below, where there will be a fairly uniform pressure over the horizontal plane.

The tests were made on a rigid base and the results may be expected to apply to a firm roadbed capable of carrying the loads transmitted. A depth of ballast greater than that named would be found useful when the roadbed is of uneven character or yields under the load or is subjected to unusually heavy load.

The tests show that for quiescent loading there is little difference in the manner and rate of transmission and distribution of pressure for broken stone, pebble, and sand ballasts; that is, at a given depth the intensities of pressure will be approximately the same, provided of course the ultimate carrying capacity of the ballast is not exceeded, and this conclusion may properly be extended to other non-cohesive materials. It will require less load to force the tie into sand ballast than into broken stone; the ultimate carrying capacity of the broken stone ballast under tie pressure is much greater than that of the sand ballast—the particles of sand ballast are more easily moved and rearrange themselves under lighter loads. For the different kinds of ballast there are great differences in the ultimate load which can be carried on a tie before ballast movement begins. The ultimate carrying capacity depends upon size of particle, smoothness of surface, and degree of angularity. A material the mobility of which under pressure is increased by the addition of water or by mixture with other materials may thereby have its carrying capacity decreased. For heavy loading the ultimate carrying capacity of a ballast material is especially important.

It is evident that a principal function of the ballast immediately under the tie and for some distance down, aside from such functions as drainage, is to carry the load without material lateral movement of the ballast to that depth at which lateral distribution becomes effective. An advantage of the coarser, rougher kinds of ballast is that they will carry a greater ultimate load—which is of special importance in the upper part of the ballast. This is especially true under the jarring, vibrating loads of track service for which the ultimate carrying capacity naturally will be less than that found under the quiescent loads used in the tests.

The tests in the laboratory indicate, as would be expected also from analytical considerations, that the presence of ballast above the level of the bottom of the tie may have little influence on the quiescent load which will be carried before the ballast will work out from under the tie and allow it to settle, but that under repeated applications of load and particularly under jarring and vibratory loads the ultimate carry-

ing capacity of the ballast is considerably increased by raising the level of the ballast surface to the top of the tie. This advantage is particularly apparent at the end of the tie, where under the whipping action of the tie under repeated deflections the particles of ballast will more readily be pushed away, since beyond the end of the tie there is no part of the track structure available for resisting the lateral pressure as is the case in the direction of the track, where another tie is always near at hand.

It seems probable that the effect of the jarring action of train loads will be to decrease the lateral distribution of pressure. It seems possible also that this tendency is counteracted in some degree by the cohesion which develops in ballast after it has been in place for some time.

It should be added that the "lines of pressure" used in the discussion are presented as being of service as an illustrative and suggestive conception which will help to explain some of the phenomena of transmission of pressure, rather than as a rigidly scientific hypothesis.

Respectfully submitted,

The Committee to Report on Stresses in Railroad Track

DISCUSSION

A. W. Buel,* M. Am. Soc. C. E. (by letter).—The results of and deductions from the experiments to determine the distribution of pressure under railroad ties draws attention to the important influence of conjugate pressures or passive resistance in the ballast. Mr. Buel.

All the published tests were made with ties rectangular in cross-section—the almost universal standard in the United States. Ties of different cross-sections have been tried in at least two cases and perhaps in others. The writer refers to the triangular tie tested on the Great Northern Railroad and to the Percival reinforced concrete tie tried on the Southern Pacific System. Some seven or eight years ago his attention was called to the Percival tie, the moment of resistance of which he found by computation to be so small that the rather favorable report of the behavior of these ties in the track seemed to be almost incredible. It was stated, however, that, when alternated in the track with the standard rectangular tie, they did not last any length of time. It was reported by the division engineer in charge that this triangular tie could not be used when interspaced with standard ties, but acted very well when used with adjacent ties all of the same kind.

From a consideration of these facts the writer came to a tentative conclusion that the conjugate pressures or passive resistance of the ballast was the cause of the Percival tie holding up when, on the simple theory of its action as a beam, it should have broken. In other words, that the shape of the tie in cross-section changed the distribution of pressure in the ballast so as to reduce the bending moment on the tie.

An investigation of the influence of the shape of the tie on distribution of pressures certainly will develop some interesting results and possibly some very valuable ones. Six years ago the writer attempted to get some interested parties to finance such a series of experiments, and when this Special Committee was organized by the Society, he suggested to its Chairman that tests on ties of different cross-sections be included. The writer hopes that, before concluding its labors, the Committee will find a way to make such a series of tests and incorporate the results in future reports.

E. P. Goodrich,* M. Am. Soc. C. E. (by letter).—The writer has studied the Second Progress Report of the Special Committee to Report on Stresses in Railroad Track with considerable interest. Mr. Goodrich.

Several comments might be made with reference to this report, but the most important is in connection with the results discussed in Article 42, "Intensity of Pressure at Different Depths Below Center Line of Tie" (page 1562). An examination of Fig. 94 and a mathematical analy-

* New York City.

Mr. Goodrich.

sis of the results there plotted show that a semi-logarithmic plot would give a formula much nearer the apparent truth than that indicated in the report—in fact, the sum of the differences is reduced more than one-half. Vertical unit pressures should be plotted to a logarithmic scale, while the corresponding depth of ballast, in inches, should be plotted to an arithmetic scale. When this is done, the experimental results are found to fall substantially on straight lines. The equation of the average straight line thus secured, determined by the method of least squares, is,

$$\log. \frac{P}{P_a} = 2.471 - 0.0443\ h.$$

Obviously, this should be inserted in Equation (27) and in subsequent equations in place of the formulas adopted by the Special Committee. When this is done, results are obtained which are more concordant with fact.

Paper No. 1456

FINAL REPORT OF THE SPECIAL COMMITTEE ON STEEL COLUMNS AND STRUTS*

WITH DISCUSSION BY MESSRS. HENRY S. PRICHARD, GUSTAV LINDENTHAL, CHARLES EVAN FOWLER, J. A. L. WADDELL, EDWARD GODFREY, WILLIAM H. BURR, R. VON FABRICE, L. J. MENSCH, AND THE STEEL COLUMN COMMITTEE.

The Special Committee, authorized by vote of this Society, "to consider and report upon the design, ultimate strength, and safe working values of steel columns and struts", was organized in January, 1909, with eleven members, as follows:

ALFRED P. BOLLER,	FRANK C. OSBORN,
AUSTIN L. BOWMAN,	GEORGE H. PEGRAM,
EMIL GERBER,	LEWIS D. RIGHTS,
CHARLES F. LOWETH,	GEORGE F. SWAIN,
RALPH MODJESKI,	EMIL SWENSSON,

J. R. WORCESTER.

Austin L. Bowman was elected Chairman, and Lewis D. Rights, Secretary.

Since that time, Alfred P. Boller, Emil Gerber, and Austin L. Bowman have died. They had brought ripe experience and enthusiastic interest to the work of the Committee, and its members desire at this time to record their appreciation of the invaluable work which these three gentlemen did while they were with us. James H. Edwards, Rudolph P. Miller, and C. W. Hudson were appointed to fill vacancies. Frank C. Osborn and Rudolph P. Miller have resigned from the Committee, on account of the pressure of other important duties. George H. Pegram, who served as Chairman after the death of Austin L. Bowman, resigned from the Committee upon being elected President of the Society, but has continued to take an interest in the work as

* Presented to the Annual Meeting, January 16th, 1918.

an *ex officio* member. Your Committee now consists of eight members, as will be seen by the list at the end of this report.

During 1909 the Committee collected literature on the subject of column tests, and tabulated and diagrammed the records of tests on columns with cross-sections of more than 5 sq. in. in area. This information was presented as a Progress Report to the Annual Meeting in 1910.* The report expressed the opinion that these data were not adequate, and that further tests were necessary.

During 1909 Congress authorized the construction of a large testing machine at Washington, and the Bureau of Standards, Dr. S. W. Stratton, Director, offered to make a series of tests on columns as soon as the machine was completed, the expense to be borne by the United States Government. The Committee and Dr. Stratton conferred as to the nature of the tests, and the Committee outlined the programme of a series of nine types of test columns, Figs. 1, 2, and 3. Owing to delays in constructing the machine, and difficulties in securing the special steel, the testing of the columns did not begin until January, 1914.

So as to provide a permanent record of the methods used, the Committee republishes below portions of the Progress Report of 1915, as follows:

Testing Machine and Instruments.

All the tests have been made at the Bureau of Standards, with an Emery testing machine, which was authorized by Congress on March 4th, 1909, and was accepted in 1913. Its capacity is as follows:

Tension	1 150 000 lb.
Compression	2 300 000 lb.
Extreme length between heads:	
Tension	34 ft. 4 in.
Compression	33 ft. 1¾ in.
Clearance between screws	4 ft. 6 in.
Length of stroke of ram	5 ft.

It will be seen from Fig. 4 that it has two heads, one fixed and the other movable, on two straining screws, each 12 in. in diameter. The hydraulic ram which furnishes the pressure is in the movable head, and, as the stroke is only 5 ft., it is necessary to adjust this head for columns of different lengths. The weighing is done from the fixed head of the machine.

The weighing device, which is peculiar to the Emery machines, consists of a specially constructed hydraulic support in the fixed head of the machine, which is connected with a smaller hydraulic chamber in the scale case. The load on the test specimen is transmitted directly to the oil in the hydraulic support, and by hydrostatic pressure is transmitted to the hydraulic chamber which actuates the levers

FIG. 3.

of the weighing scale. These levers are all of the plate-fulcra type, characteristic of all Emery testing machines.

The construction of the hydraulic support and chamber is such that a movement of 0.01 in. of the brass diaphragms is sufficient to register the full capacity of the machine. By use of these diaphragms and guiding rings, friction of the parts is eliminated.

The programme calls for all the tests to be made with square-ended columns, and this is done by providing cast-steel bearing blocks at each head, which bear directly against the columns. Considerable difficulty has been found in securing bearing blocks of sufficient accuracy, and it was necessary for the Bureau to go over all the blocks and dress them to a surface with a variation of not more than plus or minus 0.001 in.

For measuring the compressions on the longitudinal axis of the columns, compressometers were used, which consisted of a bar, fixed at one end to the column, and the other end connected with a micrometer gauge, which reads by estimate to ten-thousandths of an inch. This gauge was equipped with an electrical buzzer, which enabled the operator always to secure an equal contact. At the beginning of the series, wood bars were used, but, owing to the length of time taken in making a test, it was decided to substitute hollow steel bars, in order to avoid any possibility of changes due to moisture and temperature.

The local stresses were measured with a Berry strain gauge, which is made with a pair of Invar steel bars some 10 in. long, with a fixed point at one end and a movable point with a bell-crank at the other end. The horizontal arm is connected with an Ames dial gauge, which reads, with the multiplication of the bell crank, to 0.0002 in., and by estimating to 0.00002 in. The nominal length between the contact points of this strain gauge is 8 in.

The strain gauge measurement was made in the usual way, *viz.*, two holes were drilled, 8 in. apart, using a No. 55 drill, and then countersunk with a tool having an angle of about 110 degrees. This insures a good shoulder for the points on the strain gauge, which is highly essential for accurate work with this type of instrument. Experienced operators can secure very uniform readings within limits of plus or minus 0.0002 in.

Originally, the horizontal and vertical deflections of the column under test were measured with a piano wire, with a spring tension which was fastened to plugs set in each end of the column. Measurements were taken at the center by scales. It was found that when the ends of the column began to deflect, or warp, the local bends were transmitted to the wire, and this method was then improved by stretching the wire from a fixed frame below the column. The difficulty in securing accurate measurements from the wire to the column within limits of plus or minus 0.01 in. still remained, and it was finally overcome by abandoning the longitudinal wire entirely, and connecting the column at the center with two dial gauges reading to 0.001 in., which were supported on frames, independent of the column. Tension wires perpendicular to the longitudinal axis of the column transmitted the horizontal and vertical movements to the two gauges. Two operators were employed in manipulating the gauges, and, due to the length of time required to read these, some slight flow of metal may have taken place during the reading, but this was hardly sufficient to change the general result.

Test Columns.

The Progress Report of the Committee, of January 15th, 1913,* shows the column sections which the Committee proposed to use, together with the chemical and physical properties. The diagram of these sections and the properties are incorporated with the present report. In addition, it should be noted from this report that the programme was "arranged with the intention, as far as practicable, of eliminating all variables except that of form", and was subdivided so as to consider the effect of light and heavy sections. Three columns of each slenderness ratio, 50, 85, and 120 of $\frac{l}{r}$, were provided for

* *Proceedings*, Am. Soc. C. E., for February, 1913.

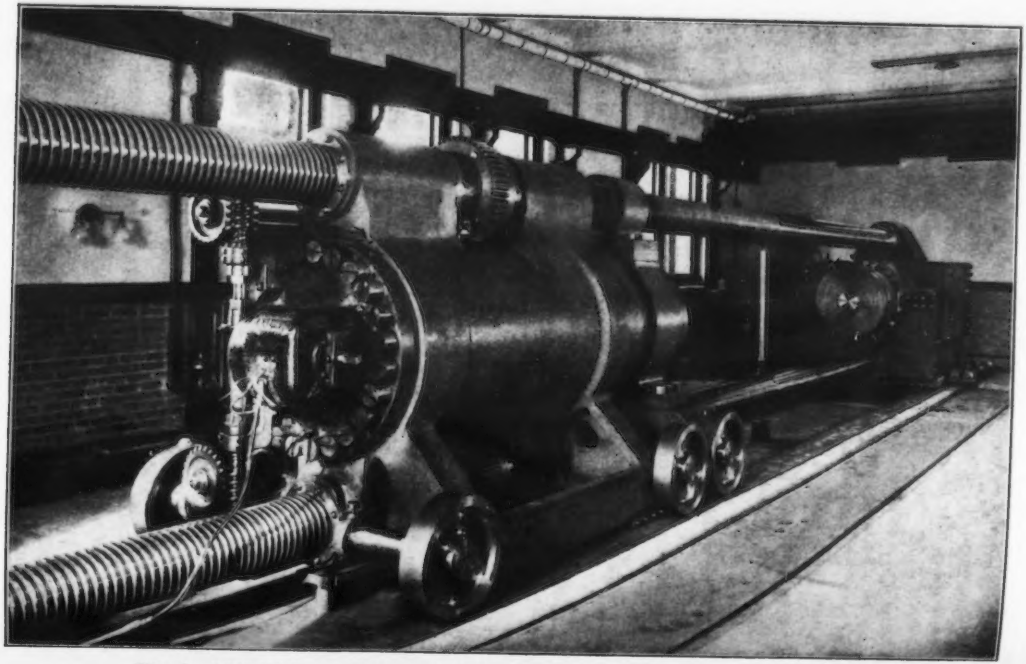

FIG. 4.—2 800 000-POUND TESTING MACHINE, BUREAU OF STANDARDS, WASHINGTON, D. C.

all shapes, making nine light sections and nine heavy sections, for each particular form of column, or a total of 144 test columns.

In addition to these, the Bureau of Standards has provided eighteen columns of Bethlehem H-sections, and eighteen columns of Carnegie 6-in. and 8-in. H-sections.

TABLE OF CHEMICAL AND PHYSICAL PROPERTIES FOR SPECIAL SPECIFICATIONS FOR UNIFORM QUALITY STRUCTURAL STEEL FOR COMPARATIVE COLUMN TESTS FOR THE BUREAU OF STANDARDS, U. S. GOVERNMENT.

Material.—Basic open-hearth structural steel.

Chemical.—Uniformity is paramount, and must be aimed for.

Carbon.—The percentage of carbon must not vary more than just to insure the desired physical properties in required sections of material.

Manganese	0.40% min. and 0.50% max.
Phosphorus	0.00% min. and 0.03% max.
Sulphur	0.00% min. and 0.04% max.
Silicon	0.00% min. and 0.10% max.
Nickel	0.00% min. and 0.05% max.
Chromium	0.00% min. and 0.05% max.
Copper	0.00% min. and 0.03% max.
All possible others	0.00%

Physical.—The desired physical properties must be aimed for.

Ultimate tensile strength	Desired, 60 000 lb. per sq. in. (may vary 1 500 lb. either way).
Elastic limit (yield point)	Desired, 38 000 lb. per sq. in. (may vary 1 000 lb. either way).
Elongation in 8 in.	Desired, 28% (may vary 2% either way).
Reduction in area	Desired, 56% (may vary 4% either way).
Character of fracture	Silky, cup.
Cold bend without fracture	180°, flat, on itself.

During the rolling of the material at the mill, and the fabrication at the shop, the inspectors of the Bureau of Standards investigated the various processes, making notes of the different conditions to which the material was subjected. Care was taken that the material met the rigid specifications, and although some variations were allowed, it was only with the special permission of the committee.

In addition to the material required for building the columns, the Bureau of Standards ordered additional pieces, 5 ft. long, of each shape and from each melt, so as to have an extra lot of unworked material on hand for special physical and chemical tests. The physical and

chemical tests were first made on all shapes by the manufacturer, and were then checked at the laboratory of the Bureau of Standards, at Pittsburgh.

It will be noted from the diagrams (Figs. 1, 2, and 3) showing the cross-sections of the columns that the rivets were all of standard size, the smallest being ½ in. and the largest ¾ in. in diameter, and the rivet spacing called for four diameters throughout the total length of the columns. It was the intention of the Committee to over-rivet the sections, so as to insure the parts acting together as a whole. So far, in no case has a failure occurred due to a bulging of the material between rivets. Where the specimens have been compressed, in order to emphasize the method of failure, the rivets in all cases have remained tight.

In general, the shop work may be described as being uniformly good, and better than the average commercial grade. The ends were dressed square to the longitudinal axis of the column, but in almost all cases it was found necessary to re-dress them, owing to the fact that the ordinary commercial milling machine gives too rough a cut to insure complete bearing over the whole surface of the end cross-section of the column. After the test column was placed in the machine, special attention was given to insure a uniform bearing by applying loads of about 1 000 lb. per sq. in.

The investigation of the test columns developed variations in their sectional areas, these amounting, in extreme cases, to as much as 4% from the nominal area. In order to determine the correct area, the shapes were first calipered at the ends of the columns, and the variations noted. Prints of both ends were taken by blackening the ends and pressing white paper against them. The area was then determined by running a planimeter around the inside and outside perimeters. Finally, the column was weighed, the weight of the rivet heads was deducted, and the area was determined by the specific gravity of the material. This area, after being compared and checked with the results of the other two methods, was adopted as the correct one to be used in determining the unit loadings. When the column was put in the machine, before being tested, it was carefully examined for loose rivets, scale, or any other conditions which might affect its strength, and, during progress of the tests, rivets were tried and any scaling was noted. After the column was placed in the machine, a nominal load, of sufficient amount to insure its being held to the proper bearings, was applied, and the compressometers were attached. For the $\frac{l}{r}$ ratios of 50, 85, and 120, the test pieces ran on an average of 10, 16, and 23 ft. long, and the compressometers were arranged respectively with bars 50, 100, and 150 in. long. The two tests given*

* The details of these tests will be given later.

will indicate the details of applying the loads, and, as stated before, after each increment of 1 000 lb. per sq. in. had been applied, sufficient time was given to read the various strain gauges.

Failure of the column was first indicated by the dial gauges, which registered a rapid increase of the deflection at the center, and by the unbalancing of the scale beam, which showed a falling off of resistance to compression. With the exception of some additional scaling, the column at this time showed no apparent change, and the pressure could be maintained for several minutes before it had a perceptible bend.

As soon as the maximum loading was reached, the instruments were taken off, and one column of each series of three was further compressed, so as to emphasize the failure, and a photograph was taken to indicate how the column failed.

Methods of Testing.

After the material was ready for the beginning of the programme of testing, a conference was held between the physicists of the Bureau of Standards and a Sub-Committee of the Column Committee as to the methods of applying the loads and measuring the strains. A general outline of the instructions to the Engineer in Charge was agreed upon, and this outline is given below. Thus far it has not been necessary to make any marked changes in the methods. On certain tests variations have been introduced, at the request of the Committee, or at the suggestion of the physicist, but, thus far, these have not produced enough variation from the general result to warrant their continuance.

Outline of Instructions for Testing.—Columns shall be weighed and gauged for sizes before being tested. In addition, inspection shall be made to determine the condition of the riveting, in order to see that the pieces are properly drawn together, especial note being made of any local conditions where the riveting has failed to do this. Observations shall also be recorded where the pieces at the ends of the members have been bent. General alignment, waves in pieces or in the column as a whole, kinks, or any other special condition shall be noted.

The ends of the columns shall be dressed flat to reduce the amount of shimming to a minimum.

The two longer series of columns, that is, those of 85 and 120 $\frac{l}{r}$, shall be counterweighted at the middle by an amount equal to one-half of the total weight of the column.

Strain gauge measurements along the length of the column, at points from 8 to 10 in. apart, shall be made at the center of the column and near both ends. The gauge points at the ends shall be

placed far enough away to avoid effects of local distortion due to the taking up of the stresses. These strain gauge measurements shall be made at each of the four corners of the column and at the center of the webs and flanges. Special shapes, such as the Z-bar and bulb angle shape columns, may require variations from this general rule in order to determine the variation in stress in the different parts of the column.

Compressometer measurements shall also be made on longer lengths, of from 50 to 150 in., in order to check the short strain gauge measurements. Four of these will be made on each column—two on the corners and one on the center of the flange, and one on the center of the web.

Deflection observations shall be made on the horizontal and vertical movements at the middle of the length of each test piece.

The condition of the cross-section of the column shall be determined by calipering the two open sides before applying the initial load, and at intervals of loading of 5 000 lb. per sq. in., in order to determine any change in the shape of the cross-section. This shall be done in as many places as may be necessary.

Initial loads of 1 000 lb. per sq. in. each shall be applied, and compression loads of 5 000, 10 000, and 15 000 lb. per sq. in. each, returning to the initial load and determining permanent sets; from 15 000 lb. proceeding with increments of 1 000 lb. per sq. in. each, determining permanent sets after loads of 20 000 and 25 000 lb. per sq. in.; also at 30 000 lb. per sq. in., if these several loads are reached before the column fails.

Horizontal and vertical deflections of the columns shall be observed at the time the longitudinal compressions and sets are measured. The general direction taken by the column when it fails, and whether due to deflection as a whole or local buckling, shall be noted.

Careful observations shall be made where the column first begins to scale, also the lines of scale. After failure, record the conditions of the rivets around the distortion points to see if any of these rivets are loose.

After the ultimate load has been reached, at least one column of each cross-section and length shall be compressed, to emphasize the manner of failure.

In general, photographs shall be taken of one column of each cross-section and length when the ultimate load has been reached, and, in addition, a photograph of each column on which the failure has been emphasized.

Examples of Tests.

The Committee gives the record of two of the tests, *Nos. 30 and 54, which contain the information as furnished by the Bureau of Standards.

* Plates XXXI and XXXII.

FINAL REPORT OF
SPECIAL COMMITTEE ON
STEEL COLUMNS AND STRUTS.

Change This Record
Form 359 a.

DEPARTMENT OF COMMERCE, BUREAU OF STANDARDS, WASHINGTON, D. C., REPORT ON TEST No. 30

Date, April 3 and 4, 1914.

For whom tested: American Society of Civil Engineers.
Type No. or designation: 1.
Marks on column: I A C 8421.
Tested with flat ends.

Counterweighted: one-half its weight at middle.
Nominal sectional area, in square inches: 11.475.
Radius of gyration: 2.94.
Slenderness ratio: 120.

Initial condition—
Bowing: Good.
Members at the ends: Good.
Alignment: Good (See note).

Length over all: 33 ft. 4½ in.
Weight in pounds: 398.
Sectional area, in square inches: 11.36. Corrected area, 11.30.
Ganged lengths: 150 and 8 in.

Applied Loads.		Compression, in Inches, in 150-in. Gauged Lengths for Positions.					Mean compression in 150-in. gauged lengths (inches).	Deflections at Middle of Length. (Inches).		40 in. from Base. Compression, in Inches, in 8-in. Gauged Lengths at Base for Positions.								Straddling Middle. Compression, in Inches, in 8-in. Gauged Lengths at Middle for Positions.								Remarks.
Pounds, total.	*Pounds per square inch.	1	7	3	4	5		Horizontal. North.	Vertical. Down.	1	2	3	4	5	6	7	8	1	2	3	4	5	6	7	8

PLATE XXXII.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXIII, No. 1456.
FINAL REPORT OF
SPECIAL COMMITTEE ON
STEEL COLUMNS AND STRUTS.

Gilbert Test Record Form 280 a.

DEPARTMENT OF COMMERCE, BUREAU OF STANDARDS, WASHINGTON, D. C.—REPORT ON TEST No. 54.

Date, July 24, 1914.

Purchaser tested: American Society of Civil Engineers.
Type No. or designation: 2.
Mark on column: 2A.
Tested with flat ends.

Counterweighted half the weight at middle.
Nominal sectional area, in square inches: 10.18.
Radius of gyration: 2.32.
Slenderness ratio: 130.

Initial condition—
Riveting: Good.
Members at the ends: Good.
Alignment: Vertical, good. Bent south 0.2 in. in center.

Length over all: 23 ft. 1½ in.
Weight in pounds: 840.
Sectional area, in square inches: 9.95.
Gauged lengths: 150 and 8 in. Corrected area, 10.09 sq. in.

Applied Load.		Compressions, in Inches, in 150-in. Gauged Lengths for Positions.					Mean compression in 150-in. gauged lengths (inches).	Deflections at Middle of Length (Inches).		Straddling Middle. Compressions, in Inches, in 8-in. Gauged Lengths at Middle for Positions.								Remarks.

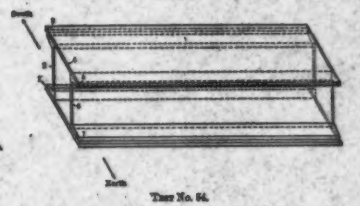
25 000	2 500	Ultimate Strength According to Corrected Area.																



Test No. 54.

*Sectional area used in computing unit loading, 9.95 sq. in. Corrected area, 10.09 sq. in. All loadings in pounds per square inch should be adjusted by multiplying by the factor, 0.9974.

FIG. 6.

A question arose as to the tendency of the material to flow under load, and, in order to secure information on this point, a special time test was inaugurated. This is given as No. 54, where it will be seen that various loadings were applied and then held while the compressometers were read at intervals of 5 min. until the flow of the metal ceased. Although the results are interesting, and might be a matter of speculation in beginning a new programme, the variation in the failure point from similar columns does not seem to show enough difference to warrant any extensive carrying out of time tests in the present programme.

As stated in the foregoing report, the programme was arranged "with the intention, as far as practicable, of eliminating all variables except that of form, and was subdivided so as to consider the effect of light and heavy sections." The Committee felt at that time that it was better to confine itself to a rather narrow programme, with the use of columns having a cross-section arranged so as to avoid lacing or battens, rather than to attempt to cover the effects of details and unsymmetrical sections. The Committee was influenced somewhat in the choice of certain forms of columns by an opinion held by some engineers that columns failed largely through the crippling of the thin outstanding legs. For example, in a discussion published in 1908,* George E. Gifford, M. Am. Soc. C. E., expressed the opinion that angles ½ in. thick would be more than twice as strong as angles ¼ in. thick; and the late T. H. Johnson, M. Am. Soc. C. E., suggested the use of bulb-angles, believing that the bulb on the outstanding leg gave stiffness to the columns. He called attention to the superior behavior of Z-bar columns, "evidently due to the support of the horizontal leg afforded by the outer leg of the Z".

On this account, the Committee selected a bulb-angle column, Type 7, and a Z-bar column, Type 8, for test, and designed a column, Type 6, made up of an I-beam with two plates riveted to the flanges. The Committee realized that this Type 6 column was not a satisfactory form, but wanted to study the effect of the outstanding edges of the flange plates. Tables 1 to 9 show the record of the column tests published in the Progress Reports of 1916 and 1917. These records call attention to the decrease in unit ultimate strength of the heavy sections when compared with the light ones. This, with the single exception of Type 6, slenderness ratio $\frac{l}{r} = 50$ (see Table 4) was true for all the different types of columns.

The results, as shown by the foregoing tests, though demonstrating the value of a thicker plate in the short columns of Type 6, hardly prove or disprove the original question before the Committee, as to

* *Proceedings*, Am. Soc. for Testing Materials.

the influence of the thin outstanding legs. It is possible that, for very thin metal, the ratio of the thickness of the outstanding leg to its width might have an effect on the strength of the column, but, for the thicknesses of the material which have been used in the programme of tests outlined by the Committee, it is evident that the ratio of thickness to width is not a controlling factor.

In seeking to account for the falling off in strength of the heavy material, the Committee learned that it was necessary to look beyond the differences in the ratios of widths to thicknesses of outstanding legs, and variations of cross-section. The only remaining element which could be charged with responsibility appeared to be the metal itself, and though the intention had been to secure material of a uniform grade, a more careful and thorough investigation disclosed the fact that the attempt had not been successful.

The physical characteristics and strength of structural steel are affected by the amount of working which it receives in passing through the rolls, and, for the same size of ingot, the heavy material does not receive as much working as the light; consequently, for the same chemical composition, the heavier material is weaker. In ordering the steel for the column tests, the Committee provided for this difference in working by allowing the mill to change the carbon content so as to endeavor to produce the same strength for the light material as for the heavy. When the attention of the Committee and the Bureau of Standards was drawn to the falling off in the unit strength of the heavy material, the Bureau of Standards investigated the record of the physical and chemical tests made at the mill when the steel was rolled. The complete record of these physical and chemical tests is shown in Table 10, and it will be seen that this record gives no indication of the difference in strength between the heavy and light material.

A note concerning the choice of the original specifications might be in order before commenting on the record of specimen tests.

At the time the Bureau of Standards offered to make the column tests, Dr. Stratton requested the Committee to write the specifications and secure prices. It was desired to have the material for the columns as nearly uniform as possible, the thought being to have as much of it as possible come from a single heat. The specifications (page 1591) are the result of the conference of the Committee with the steel manufacturers, and, as stated before, they are very much more rigid than the average structural specifications. The Committee accepted some material which did not fully meet the rigid specifications, but it was considered at that time to be fully equal to, or better than, the ordinary grade of structural steel, which has an allowable variation of 5 000 lb. per sq. in., more or less, from a desired ultimate strength of 60 000 lb. per sq. in.

* Not within limits of specifications.

Not finding an explanation of the falling off in strength of the heavy material in the record of mill specimen tests, the Bureau of Standards then took some of the long columns, which had already been tested, and cut them into lengths to give a slenderness ratio of $\frac{l}{r} = 20$.

These short columns showed that the unit ultimate strength of the heavy columns was considerably more than that of the light ones. Both series indicated a fairly definite point at which permanent set occurred, and showed that this point was lower for the heavy columns than for the light ones, indicating that the increased ultimate strength of the heavy ones came about from the block action of the short, heavy material, and that the elastic limits or yield points are the true indicators of the strength of the two different thicknesses of material. See Fig. 5, from the 1916 Progress Report.

Tests of short columns having a slenderness ratio of $\frac{l}{r} = 20$, made of material which had not been previously stressed, confirmed these results and the belief that the strength of columns is governed, not by the ultimate tensile strength of the material, but by the point at which there is marked departure from an elastic condition. See Fig. 6, from the 1917 Progress Report.

To investigate the question of this critical point, the Bureau of Standards proposed some supplementary specimen tension and compression tests, to be made from pieces, 5 ft. in length, which had been provided from each melt at the time the material was rolled. These 5-ft. pieces were in the nature of coupon material from the columns, and had not been subjected to stresses in the testing of the columns.

Tables 11 to 15 show the record of the supplementary specimen tests made on the coupon material ordered from the same melts as the material for the full-size columns, and Table 22 is the summary of the averages of Table 10 and Tables 11 to 15. When we compare the results shown by Tables 11 to 15 with the mill specimen tensile tests made from these same melts, Table 10, and both with the table of full-size column tests, it will be seen that the ultimate tensile specimen strength is not a correct indicator of the strength of the columns. The ultimate strengths shown on the supplementary specimen tests are very close to the ultimate strengths given for the specimen mill tests, and neither the ultimate strengths from the supplementary tests nor from the mill tests indicate the falling off in strength of the thicker material. It is also evident that the yield point, as recorded by the ordinary commercial tensile specimen tests, even when the machine is run at comparatively slow speeds, as was done in the Pittsburgh Laboratory of the Bureau of Standards, does not give the correct index of the

strength of the material. It appears necessary, therefore, in order to predict the strength of a column, to determine the nature of the metal by some other means than those generally used.

In the Progress Report of 1917, the Committee mentioned the discussion held by the American Society for Testing Materials at its Annual Meeting, June, 1916, on the relation between proportional limit, elastic limit, and yield point. For the purpose of studying the column tests, the Committee gave careful consideration to this discussion to find whether it was possible to determine some point which, for practical purposes, might be easily located, clearly defined, and at the same time represent the limit where the metal ceases to have structural value. None of the terms defined by the discussions of the American Society for Testing Materials has appealed to the Committee as having these qualities. In searching for a more satisfactory definition, the Committee considered a modification of the suggestion made some years ago by the late J. B. Johnson, M. Am. Soc. C. E. The Committee has defined the critical point as the point which is determined graphically by drawing a line tangent to the envelope of the stress-strain curve, having a slope of one-half that of the last run-up line for its straight, or nearly straight, portion.

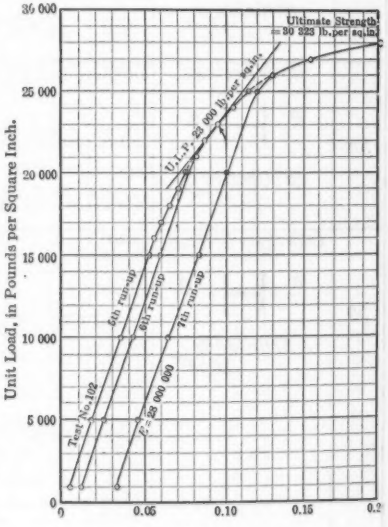

FIG. 7.

Fig. 7 illustrates this method of determination. So as not to confuse this with former definitions of yield point or elastic limit, the Committee has adopted a new term, and calls this the Useful Limit Point, or U. L. P.

In straining a column, there is a point beyond which its structural value is uncertain, and consequently unsafe to rely upon. This point lies somewhere above the region of perfect elasticity and well below the place where manifest yielding occurs. For the study of column tests, the U. L. P. as above defined seems to fulfill these conditions satisfactorily. Careful observations and plotting of the stress-strain curve locate it without chance for controversy. It will be noted that the method is applicable to both tension and compression tests.

The Committee has carefully considered the application of this method to the stress-strain diagrams of full-size columns. Tables 16 to 21 give the U. L. P. (Useful Limit Points) for the column tests, together with the average for the three of each series, also the ultimate strength, so that comparison may be made between the values of the U. L. P. and the ultimate strengths, and Plates XXXIII, XXXIV, and XXXV are given as samples to illustrate the method used by the Committee in determining the U. L. P. values. To publish all the diagrams used in these investigations would cost the Society a large sum of money, and the Committee is of the opinion that such publication in this report is not necessary. At the completion of the work of the Committee, the tracings of the diagrams will be filed in the Engineering Societies Library, and they can be reproduced at a nominal expense for those engineers who desire to make a special study of this phase of the work.

It will be seen from a study of the tables of U. L. P. values that this method offers an extremely valuable indication of the strength of full-size columns. It will be seen, further, that the shape of the cross-section of the columns, as covered by the programme of the Committee, is of minor importance when considered in connection with the strength of the material, as shown by the U. L. P. values.

As mentioned above, and as will be seen from Tables 11 to 15, the specimen coupon tests are not complete. The Bureau of Standards planned to carry on a very elaborate supplementary investigation during 1917. For some time, however, the testing capacity of the Bureau has been given over to testing materials for war purposes. The tests here published show all that Dr. Stratton can promise until the close of the War. The Committee feels that the results shown by these tests would not be changed materially by additional tests in the series, and, realizing the demand for information on the subject, desires to make a final report based on the available data.

The data mentioned above, namely Tables 1 to 21, inclusive, showing the values of the U. L. P. (Useful Limit Points), furnish all the information which the Committee has obtained in accordance with the first item of its commission—to determine the ultimate strength of steel columns and struts. In making this as a report, the Committee has not attempted to correlate these tests with the older ones shown in its report of 1910. Some of the columns given in the 1910 report were tested many years ago, when it was not thought necessary to have such accurate measurements as have been made in the present series. To attempt to correlate the older column tests with the present ones would, in the opinion of the Committee, be of no value except as a general speculation.

It will be seen at once from the study of the foregoing tables that the record is unsatisfactory, on account of the large variation in ultimate strengths and U. L. P. (Useful Limit Points) of the columns. Some

of this variation may be brought about by the shape of the column, but most of it can be explained by the condition of the material. Plate XXXVI is a summary of the curves of all the U. L. P. values. A surprising feature of these curves is the variation in U. L. P. of 15 000 lb. per sq. in. between columns of Types 5 and 5*B*. The average U. L. P. for $\frac{l}{r} = 50$, for columns of Type 5, light section, is 34 700 lb. per sq. in., and for Type 5*B*, extra heavy section, it is 19 700 lb. per sq. in. The lower value is but 57% of the higher, and there is a variation of 28% from the mean. These extreme variations may be abnormal, but it must be remembered that the tests were made on material specially chosen, and supposedly the best that the mills could produce.

On account of this large range in the results, it is not possible for the Committee to execute satisfactorily the first portion of its commission, which was to determine the ultimate strength of steel columns. The Committee does not believe it is safe to take the average strength of all the columns which the Bureau of Standards has tested as a basis for the design of columns where there is uncertainty as to the quality of the material. In order to make a constructive report, therefore, it is necessary to consider the second part of the Committee's commission, namely, to determine the safe working value for columns, and to make this a safe working value conservative enough to cover the wide range in the results shown by the Committee's programme.

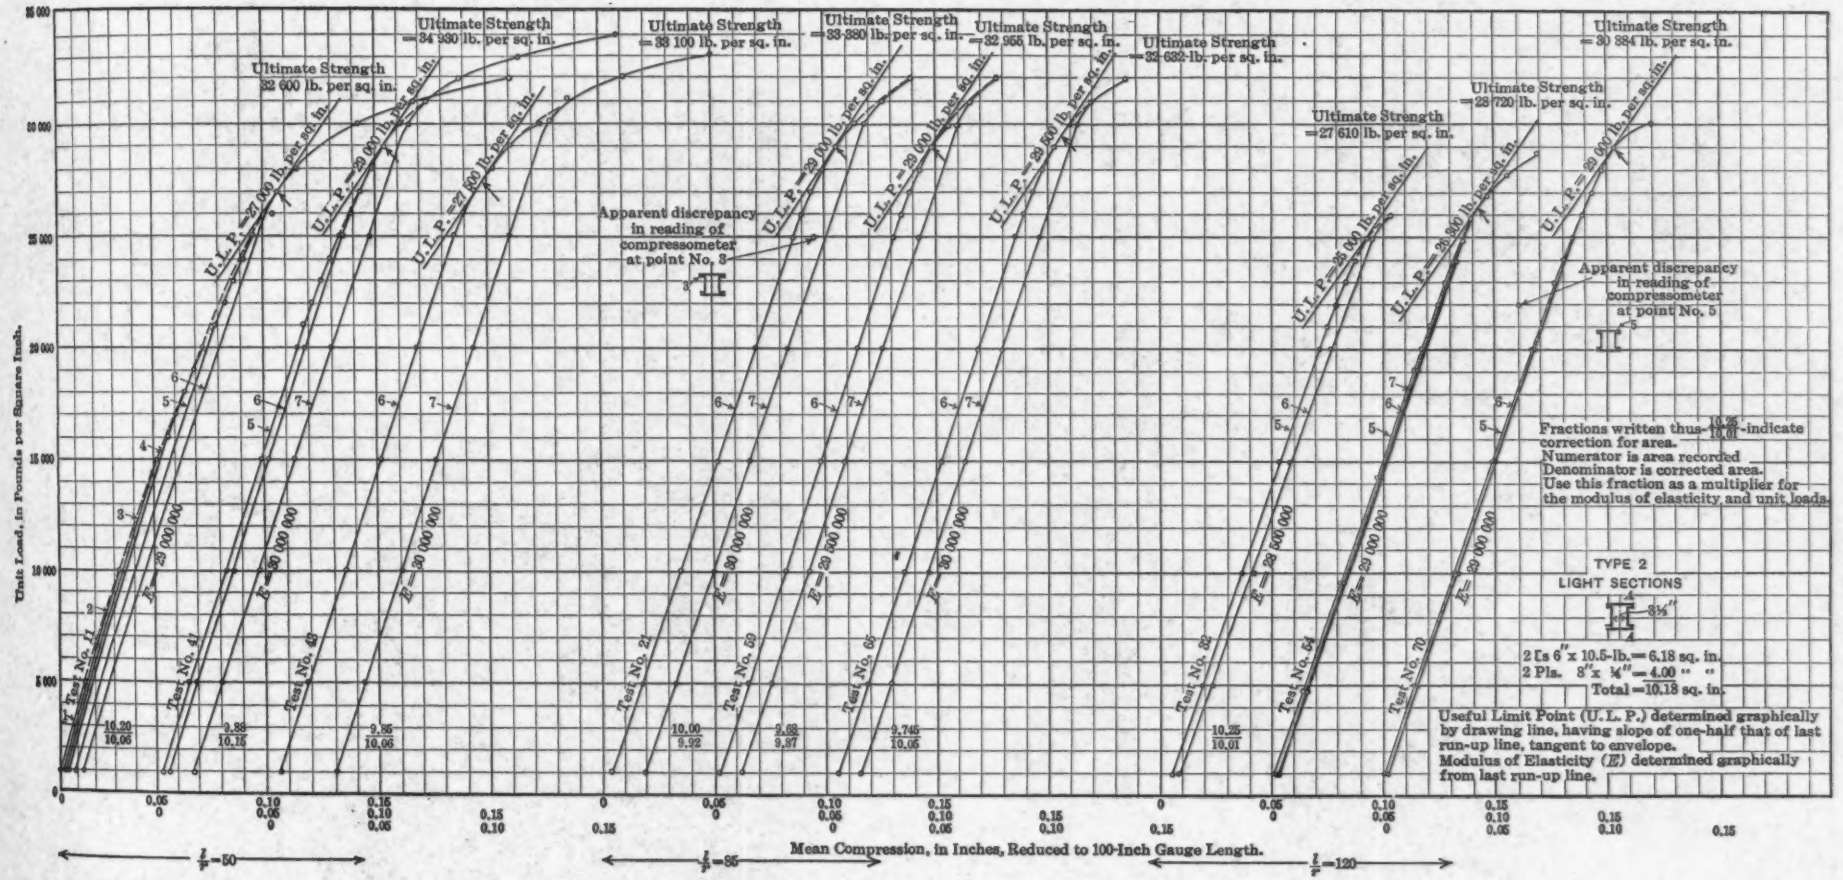
In considering the safe working value for a column, it is necessary to take account of a number of uncertain and sometimes unknown factors. Some of these might be enumerated as follows:

(1) Material:
  (*a*) Quality of steel.—High and low carbon.—Amount of work received.
  (*b*) Uniformity.—Segregations.—Hard and soft spots.
  (*c*) Workmanship.—Initial bends.—Inadequate or poor riveting.

(2) Condition of loading:
  (*a*) End bearing.—Pin or square ends.—Ends not milled perpendicular to axis.
  (*b*) Eccentricity.—Load not applied at axis of column.
  (*c*) Transverse loading.—Combined beam and column action.
  (*d*) Repeated stresses.—Loads repeated and perhaps alternated many times.

(3) Use:
  (*a*) Overloading.—Impossibility of always determining exact loading.
  (*b*) Secondary stresses.— Sometimes a considerable proportion of the primary stress.

PLATE XXXIII.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXIII, No. 1456.
FINAL REPORT OF
SPECIAL COMMITTEE ON
STEEL COLUMNS AND STRUTS.



(*c*) Deterioration or corrosion.—Exposure to corrosive elements.

(*d*) Facilities for inspection.—Forms of columns which may be frequently and easily examined.

(*e*) Warning of failure.—Practically no warning, as compared with tension members.

(*f*) Gravity of injury caused by failure.—Damage to life and property in some cases, or only temporary inconvenience in other cases.

(*g*) Cost of replacement.

In the early days of the iron and steel industry, it was the custom of engineers to adopt a working unit stress for tension members of one-quarter of the unit ultimate specimen tensile strength, and they spoke of a factor of safety of four. When we consider the distortions produced by the stretching of tension members after being strained above the yield point, and that manifest yielding and failure occur in columns when the stress reaches about one-half of the specimen ultimate strength in tension, it is evident that the factor of safety obtained by this older method was nearer two than four.

In a structure having both tension and compression members, the desideratum in determining a factor of safety is to obtain a working stress so that all parts of the structure have an equal capacity to resist the applied loadings.

Your Committee has made no original investigations of the strength of full-size riveted tension members, and, therefore, cannot make as definite a comparison with full-size riveted columns as would be desirable. It may be stated, however, that the usual working stress in tension is approximately one-half the elastic value of the metal, and the Committee assumes that, in view of all the factors mentioned above, columns should have a safety factor of at least two, based on the U. L. P., in order to be on a parity with tension members.

The average U. L. P. of all the column tests in the Committee's programme for slenderness ratios, $\frac{l}{r} = 50$ and $\frac{l}{r} = 85$, is 27 200 lb. per sq. in. The U. L. P. for the extra heavy section, Type 5*B*, slenderness ratio $\frac{l}{r} = 50$, which is the lowest value observed, is 19 700 lb. per sq. in., which is 28% below the average, and this appears to be too wide a margin of under-run for safety. It would seem to be necessary, therefore, in recommending a working stress, to assume a U. L. P. lower than the average of all the tests. If we take as a safe assumption the mean between the lowest value and the average value, this mean will be 23 500 lb., or approximately 24 000 lb. per sq. in. The factor of two applied to 24 000 lb. will give a safe working value

of 12 000 lb. per sq. in. for columns, which stress the Committee would recommend. In this recommendation it is assumed that we are dealing only with static loads, and that a percentage of the static stress will be added to cover the impact due to moving loads.

Lacking further experimental data, the Committee regards it as unwise to assume a higher working stress than 12 000 lb. per sq. in. for columns in which the ordinary grade of structural steel (60 000 lb. ultimate tensile strength desired), is specified. It is, of course, impracticable to know in advance the precise U. L. P., or any other factor of strength, which the metal used may develop. It would be possible to specify the desired value, and, in important structures, to inspect the material with sufficient care to insure the rejection of all which failed to come up to the specification. Later in the report, suggestion is made of a method whereby those engineers who have ample facilities for testing materials may adopt such working stresses as are warranted by the special material tests. It must be remembered, however, that a large portion of the material which is classed as structural steel is furnished on the manufacturer's specifications, and, in view of the Committee's findings, probably most structural steel is incompletely tested.

The Committee would recommend that this working stress of 12 000 lb. be used for columns up to a slenderness ratio of $\frac{l}{r} = 80$, and, above this slenderness ratio, the Committee would reduce the working stress to allow for uncertainties. The Committee realizes that the results as given in its programme show that the slenderness ratio has a comparatively small effect, up to values of $\frac{l}{r} = 120$. It must be remembered, however, that the tests were made by the Bureau of Standards under extremely favorable conditions, the ends of the column being scraped so as to give a bearing precisely perpendicular to the axis of the column. The Committee would recommend a working stress of 8 000 lb. per sq. in. for a slenderness ratio of $\frac{l}{r} = 120$, and that the working stresses for slenderness ratios between 80 and 120 be determined by interpolation.

The Committee realizes that the working value recommended for short columns is lower than that given by the American Railway Engineering Association formula, which has been in use for a number of years. Originally this formula was $\frac{P}{A} = 16\,000 - 70\,\frac{l}{r}$ and, later, the upper section was truncated to a maximum working stress of 14 000 lb. The Committee feels, in view of its studies in regard to the U. L. P., that there is no warrant for high working stresses in short columns.

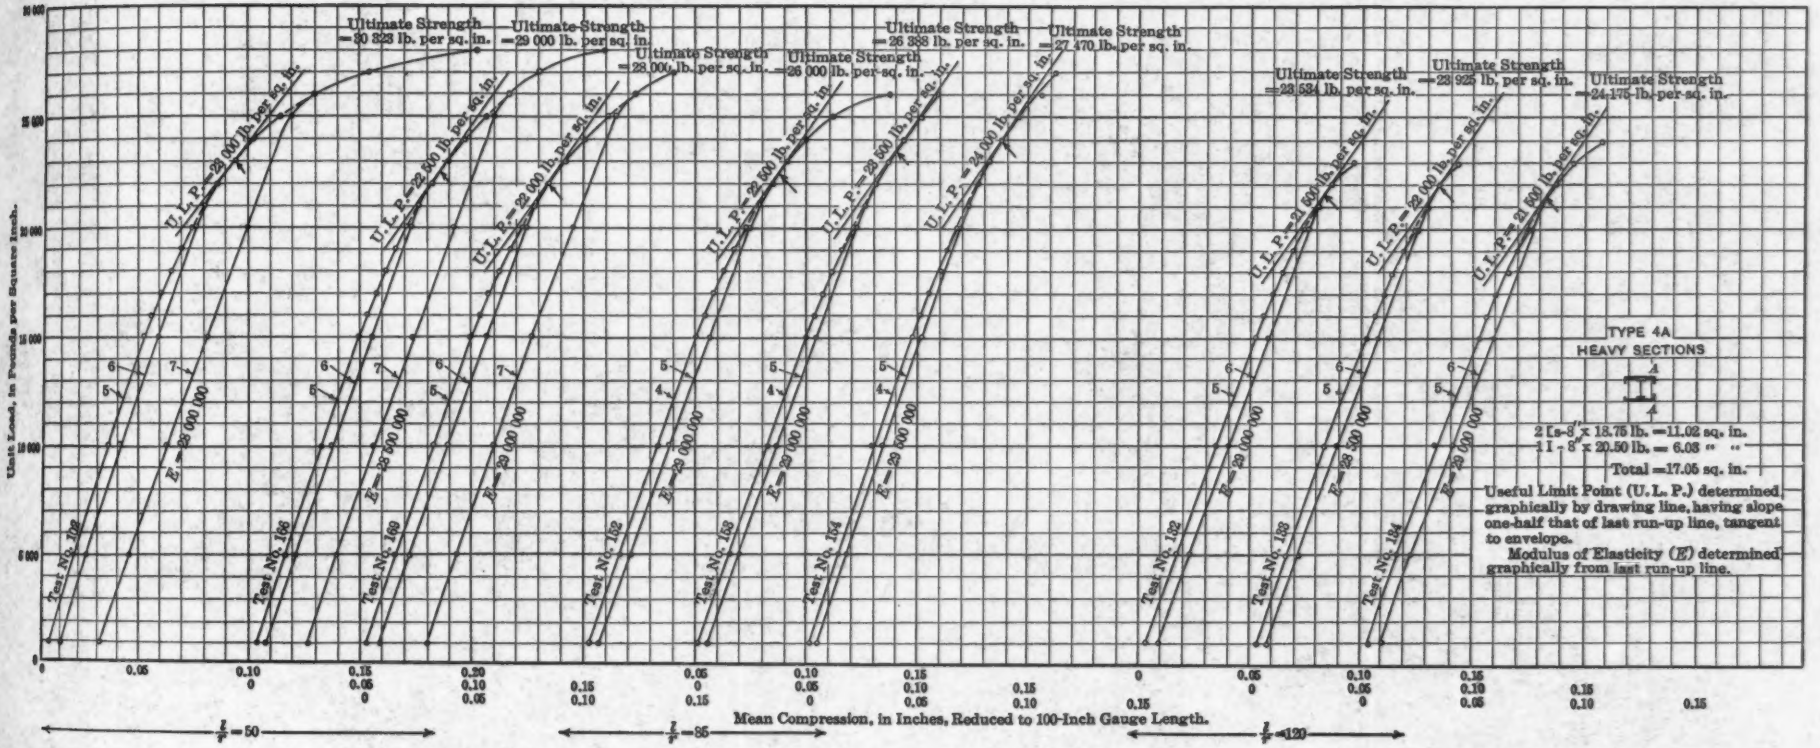
FINAL REPORT OF
SPECIAL COMMITTEE ON
STEEL COLUMNS AND STRUTS.



TYPE 4A
HEAVY SECTIONS

2 [s-8" x 18.75 lb. = 11.02 sq. in.
1 I - 8" x 20.50 lb. = 6.03 " "
Total = 17.05 sq. in.

Useful Limit Point (U. L. P.) determined graphically by drawing line, having slope one-half that of last run-up line, tangent to envelope.

Modulus of Elasticity (E) determined graphically from last run-up line.

Argument might be made that higher working values than those recommended by the Committee have been in use for long periods of years, without failure, but the Engineering Profession does not need to be reminded of accidents which have been caused by the failure of columns. Furthermore, it is evident that the present processes used in the manufacture of steel do not produce a uniform material, and that the present methods of testing do not give a correct indication of the compressive strength of the material.

The difference between the strength of the material as indicated by the mill tests made in the ordinary commercial manner and the same material when fabricated into columns is strikingly shown by Table 22. It will be noted from the portion of the table giving the values for the specimens tested at the mill that neither the "yield points", as indicated by the drop of the beam, nor the ultimate strengths, bear any consistent relation to the U. L. P.'s, or ultimate strengths,

of the full-size columns. In most cases, material which gave the lower strength in the full-size columns gave the higher "yield point", as indicated by the mill tests, and, on the other hand, the U. L. P.'s of the specimens, as determined by the Bureau of Standards, bear a very definite and constant relation to the U. L. P.'s of the full-size columns. While the studies of the Committee point to a method whereby the strength of material for columns may be correctly determined, until some such method has been generally adopted, the Committee must recommend a conservative safe working value.

The Committee has not attempted to determine safe working values for columns with a slenderness ratio above $\frac{l}{r} = 120$. Some tests have been made and recorded for a slenderness ratio of $\frac{l}{r} = 155$ which may serve as a guide to engineers, but the Committee does not feel that these data are sufficient to carry its recommendation higher than a slenderness ratio of $\frac{l}{r} = 120$.

The Committee's report covers only sections designed to avoid the necessity of latticing or battens, and tested with square ends. It has not been possible to consider the effect of different arrangements of the ends. Details, such as lattice bars, tie-plates, batten-plates, and pin-plates, have not been considered, because the Committee felt that the more important factor was the strength of the material in the columns, and that the question of details could be left until later. The Committee would refer engineers to the reports of the Committee on Iron and Steel Structures of the American Railway Engineering Association, which has worked in co-operation with your Committee, and has considered some of the details mentioned above.

Your Committee's report covers only one grade of steel, which is the ordinary structural grade, with a desired ultimate tensile strength of 60 000 lb. per sq. in. Your Committee has not considered, except in a very general way, the question of transverse loadings, repeated loadings, and long-time tests, and these features will have to await the accumulation of additional data.

The Committee realizes the demand of many engineers for a scientific, rational column formula. Numerous theoretical formulas have been promulgated from time to time, all of them based on entirely elastic material of uniform grade. At the present time it seems useless to the Committee to attempt to write a rational column formula, from a theoretical standpoint, with the possibility of variations of 28% in the strength of the material.

* Test No. 66 omitted in taking averages.

The careful selection of specimens located by the inspector, and the testing of these with extensometers, means an increased cost of the material, both to the rolling mill and to the purchaser. The Committee believes, however, that the resultant saving and the assurances of safety for large tonnages and important structures would warrant such increased expense. Possibly such inspection, if extensively carried out, would improve the methods of manufacture of steel, thereby producing a more uniform material.

To those engineers who desire to undertake such inspection, the Committee would recommend the study of Table 23, which shows the comparison between the U. L. P.'s of the specimen tests, and the U. L. P.'s of the full-size tests. As before stated, the Bureau of Standards has not been able to supply the Committee with the full quota of specimen tests. It will be seen that, where only a few specimen tests were furnished, the complete record of the material, so far as relates to the condition in the flange and the root, cannot be satisfactorily averaged, but the Committee is giving all the information that it has at hand. Some of the specimen tests were made in tension and some in compression, and these tests from different parts of the cross-sections of the columns were weighted in proportion to arbitrarily assumed areas. The data are too meager to warrant a recommendation as to the use of the average of these percentages in the design of future columns, but they may serve as a guide to those engineers who desire to begin investigations. As most specimen tests are made from the long legs of angles and the webs of I-beams and channels, on account of the convenience in securing the specimens, the table giving the percentage of the U. L. P. of full-size columns below web specimens should afford the best guide as to what might be the probable U. L. P. strength of full-size columns after the specimen U. L. P. was known.

As stated in the beginning of this report, your Committee has been in service for nine years, and it is the feeling of its members that collateral lines of investigation can be carried out by the appointment of a new Committee, rather than by the continuance of the old one.

Complete records of the work of the Committee will be filed in the Engineering Societies Library. At the close of the War, the Bureau of Standards may be in a position to complete the programme of testing the coupon material set aside for specimen tests, and the Committee has the assurance of Dr. Stratton that the record of this result will also be available for the files of the Library.

Your Committee desires to express thanks to the Bureau of Standards, which provided the tests on which this report is based, and to Dr. S. W. Stratton, Director, and his assistants, who made many investigations and suggestions, for their loyal co-operation and support.

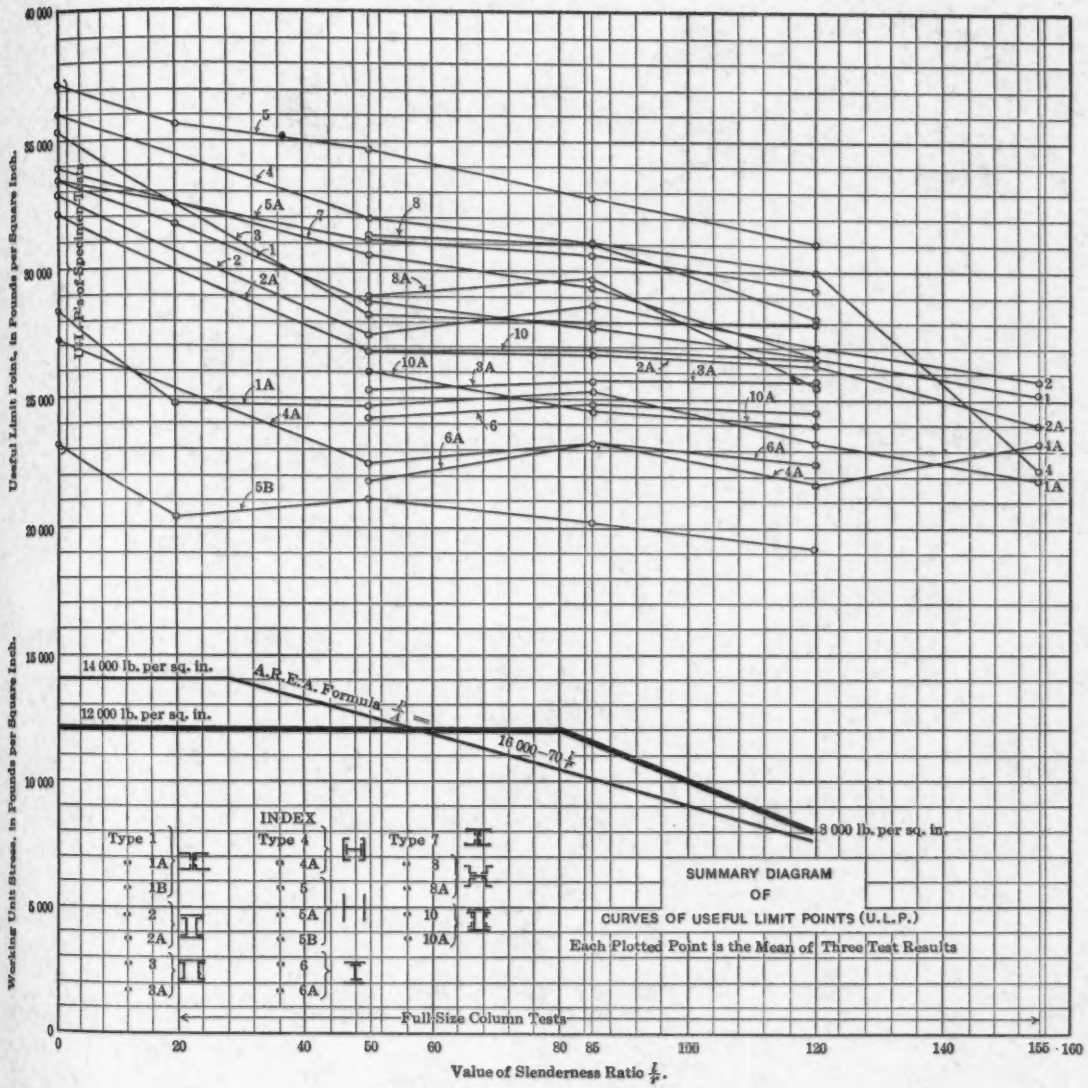
FINAL REPORT OF
SPECIAL COMMITTEE ON
STEEL COLUMNS AND STRUTS.



Believing that the foregoing report completes the work which the Committee can at present perform to advantage, it now asks to be discharged.

For the Committee,

LEWIS D. RIGHTS,
Chairman.
C. W. HUDSON,
Secretary.

COMMITTEE:

JAMES H. EDWARDS,
C. W. HUDSON,
CHARLES F. LOWETH,
RALPH MODJESKI,
LEWIS D. RIGHTS,
GEORGE F. SWAIN,
EMIL SWENSSON,
J. R. WORCESTER.

NOVEMBER 22D, 1917.

DISCUSSION

Mr. Prichard.

HENRY S. PRICHARD,* M. AM. SOC. C. E. (by letter).—The Committee is to be congratulated on its fine presentation of the results of the tests conducted by the Bureau of Standards. As a progress report, it is admirable, but the writer thoroughly endorses the sentiments which Clement E. Chase, Jun. Am. Soc. C. E.,† has expressed, in a letter just received from him, as follows:

"In reading what the Column Committee of the American Society of Civil Engineers are to present next week as their Final Report, I fail to see why they should consider their task at an end. They seem to have answered so few of the questions that have been raised in recent years as to column action, and to have passed so lightly over what has been done in the past in the way of experiment, analysis and discussion. I think their concept of a Useful Limit Point a good one, getting away from the controversial elastic limit, but I do not see that they give any evidence that what they call the U. L. P. is the useful limit.

"I expect to get down to the meeting next week, and have been wondering what would develop there. I wish that there were some way of continuing the Committee in existence, changing its personnel if the old members are tired of their work, for it seems hard to get Special Committees appointed in the Society. It would not be possible to do much in the way of testing during the war, but some planning of the next series of tests could be accomplished, and there would not be the effect of calling this report the Final and best that can be done after nine years of deliberation. If you agree and think that anything could be accomplished by discussion of the Report, or letter, in time for action at the Annual Meeting, I wish you could see your way to start something."

Why should the Committee consider its work at an end? There are many open questions that need further investigation before they can be answered; and there is much that has been done in the past in the way of experiments, analyses, and discussion which the Committee has passed over lightly but of which it is desirable that a Final Report should include an epitome and an appreciation.

The point in testing where the rate of deformation becomes double the elastic rate has been adopted by the Committee as useful for practicable purposes and termed the "Useful limit point". "Double rate of deformation point" would be a better name, as it is accurately descriptive and does not commit the Committee to a characterization of the significance of the point as an indication of strength.

It has not been shown that the metal in a structural member ceases to have structural value when the rate of deformation of the member becomes double the elastic rate. In fact, Test No. 102, used by the

* Pittsburgh, Pa.
† Now Assoc. M. Am. Soc. C. E.

Mr. Prichard.

Committee to illustrate the determination of the point where such a rate of deformation occurs, shows that, at the cost of a slight permanent set, the column became seemingly elastic to a higher point.

As regards specimen tests, the results tabulated by the Committee do show that the averages or means of the "Useful limit points" or "Double rate of deformation points", as the writer prefers to call them, of the coupons of the material of which the columns are composed, indicate, approximately, the ultimate strength of those columns which have a slenderness ratio of $\frac{l}{r} = 50$. The average ultimate strength of the thirty-three columns compared was 32 670 lb. per sq. in., though the average of the means of the "Double rate of deformation points" of the specimens was 32 080 lb. per sq. in.; and in no case was the ultimate strength of the columns less than the mean of the "Double rate of deformation points" by more than 3½ per cent. This close relationship, which the report of the Committee shows, between the mean of the "Double rate of deformation points" of the specimens representative of a column, and the ultimate strength of the column, is a valuable contribution to engineering knowledge; but there remain many important questions, some of which can probably be answered by a study of the results of past experiments. The work of the Committee could be continued with advantage to the Profession.

Mr. Lindenthal.

GUSTAV LINDENTHAL,* M. AM. SOC. C. E. (by letter).—This final report, giving the results of investigations and tests continued through seven years, will no doubt be regarded by structural designers as an authoritative guide in the proportioning of steel columns of such forms and in such cases as those to which the conclusions of the Committee are applicable.

The Committee was entirely justified in giving warning (page 1626) that in considering the safe working value for a column it is necessary to take account of a number of uncertain and sometimes unknown factors. The Committee then enumerates fourteen such factors, divided into three groups (Material Condition of Loading, and Use). One factor, however, is not mentioned, and, like any of the others, it may have a deteriorating effect on the strength of the column under certain conditions; that is, the factor of the rivet holes when the column section is made up of different steel shapes riveted together into one column.

The rivet holes in columns quite frequently do not match accurately, notwithstanding the usual reaming to bring the holes to a fit. When the section is made up of three or more thicknesses, the holes in the inside plates, after reaming, may be oblong rather than round. The rivet, after driving and upsetting, may fit the hole tightly near each rivet head, but not always in the middle of the rivet. Moreover, the

* New York City.

Mr. Lindenthal.

diameter of the rivet after cooling may be slightly smaller than the rivet hole. Most so-called tight rivets can be pushed out of the holes easily after one or the other rivet head is cut off. It cannot be claimed, therefore, that the rivets fill the holes so completely as to equal the solid metal before the holes were punched or drilled out. The rivet in the hole, also, frequently has scale on it, forming a hard film without strength. If that film is only $\frac{1}{2000}$ in. thick, then the rivet would be $\frac{1}{1000}$ in. smaller than the hole. Even with good workmanship, the fit for part of a tight rivet is more frequently less than $\frac{1}{1000}$ in. It is evident that rivet holes weaken a compression section as well as a tension section.

A plate, for instance, 12 in. wide and 1 in. thick, with four rivet holes $\frac{3}{4}$ in. in diameter, on a horizontal section has a net section of 9 sq. in., which is its value for tension; but, for compression, the universal practice is to assume full 12 sq. in. as resisting the compressive stress. Have we any good reasons or tests anywhere to show that this assumption is justified?

It is obvious that the rivet hole must flatten before the metal in the rivet can participate in the compressive strength of the cross-section. It means (assuming a modulus of elasticity of 30 000 000) that the unit stress on the steel of the net cross-section must exceed 30 000 lb. before the rivet hole will flatten $\frac{1}{1000}$ of its diameter and before the rivet can take up a share of the compressive strain in the column, which, by that time, would be 22 500 lb. per sq. in. on the unperforated cross-section. The elastic limit of the steel will thus be passed on the net section long before it is reached in the unperforated cross-section. Failure of the column by crushing or by buckling may thus be initiated in the over-stressed metal of the net section, and thus the low compression value based on the cross-section of riveted columns may be explained.

If this reasoning is correct, then the cross-section of a column is weakened in proportion to the rivet holes. That view has induced the writer, in his practice, to formulate the rule that the compressive stress shall be computed, not on the cross-section of the column, but on its net section, similar to the practice for riveted tension members. It is certainly on the side of greater safety, more particularly for the reason that failure of a steel frame structure (designed by the usual specifications), if loaded to destruction, would surely come first through the buckling of the compression members before any tension member would give way. The general belief that our framed steel bridges have a factor of safety of from 3 to 4 needs to be corrected. Frequently, it is not more than 2, but that includes the dead load. It is an ample margin for heavy structures, but hardly enough for lighter ones.

Mr. Lindenthal.

The writer has attempted a series of tests, with the object of clearing up this point of the weakening of columns by rivet holes, and for these has used rolled steel pipe sections, some unperforated and others perforated and the holes filled with rivets. The tests were made at the laboratory of the United States Bureau of Standards in Pittsburgh, but were not concluded. Such tests, however, should be continued until this question is definitely cleared up.

One of the most remarkable points brought out in the tests by the Committee is the great difference in the compressive strength of the Bethlehem H sections, referred to in the report as Sections 5, 5*A*, and 5*B* (Tables 15 and 19). That the U. L. P. should be 34 700 for the light section and only 19 700 for the extra heavy section of the same type (page 1626) and for the same slenderness ratio (50), may be astonishing until we consider that the lower temperature at which the lighter section was very probably finished in rolling, as compared with the heavier section of the same type, must have a great influence on its value as a column. The lighter section is thus provided with a hard skin, possibly not more than $\frac{1}{20}$ in. thick, which is stronger than the metal underneath. That harder metal has a higher elastic limit, and thus can better resist the fiber strains from bending and buckling before final collapse. This view derives confirmation from the fact mentioned by the Committee (page 1612) that in short lengths and for the same ratio of l to r (when the metal is exposed almost solely to block action) the differences in compressive strength disappeared.

The recommendation of the Committee that the testing of steel columns should be continued is well founded. We need to know more about the behavior of riveted column sections as compared with solid sections of the same size. Measurement with the extensometer would show whether the compressive strain in columns is uniform for the entire length or whether the steel is stressed higher in the plane of the rivet holes. To establish this fact satisfactorily, the rivet spacing should not zig zag, but, experimentally, be on straight lines at right angles to the axis of the column. Such measurements should be made and compared on solid, rolled, unperforated, tube sections, and on others which have been perforated.

The definition and establishment of the U. L. P. (Useful Limit Point) by the Committee is commendable and worthy of general adoption. Also, the use of round figures for compressive unit stresses (similar to the practice for tension unit stresses) in place of the senseless refinement (by 10 and 20 lb. per sq. in., as given in some tables) derived from the too pedantic use of compression formulas.

Mr. Fowler.

* New York City.

Mr. Fowler.

wonderful devotion its members have shown in this most essential experimental work. Yet it is apparent that the scope of the inquiry must be broadened if future investigations are to reach the desired result.

There must be a determination of the essential details of built-up columns necessary to develop the greatest possible percentage of main sections; a determination of the principal riveting, together with the effect of riveting as respects the deduction for rivet holes; a means of procuring high steel of a uniform quality; and, lastly, an accurate means of determining the stresses due not only to live and dead load, but including impact, secondary stresses, temperature stresses, and initial stresses in the steel, to the end that there may be used a very much higher unit stress than the one proposed, thus reaching an economy and efficiency in bridge design from which engineers have departed so widely in the past twenty years.

When the writer was Bridge Engineer of the Hocking Valley Railway, in 1887, the pendulum was just beginning to swing back from the era of light loads and high unit stresses, which had resulted in bridges of the lightest type, where "the pins only held by the grace of God, and where the wind stresses had to slide down the end posts." The loading then beginning to be used was thought to be phenomenal—two 92.3-ton consolidation engines and unit stresses below 10 000 lb. per sq. in. were discussed. During the period from 1890 to 1898, in which the writer was Chief Engineer of the Youngstown Bridge Company, the pendulum swung far, and Cooper's E-40 and other heavy loadings came into vogue; and though engineers still clung to their factors of safety, unit stresses as low as 6 000 or 8 000 lb. per sq. in., based on factors of ignorance, were used on the primary members of bridges.

Thus, up to the present, has been kept up the increase of loadings and the reduction of unit stresses, until engineers have wandered far from that efficiency which they must have, under the new economic and trade conditions that are dawning. Engineers must know the stresses with certainty, they must have the best and most uniform high steels, so that they may safely use the highest logical unit stresses.

During the middle Eighties the Forth Bridge was built, and there was used in the compression members a high steel of from 76 160 to 82 880 lb. per sq. in., ultimate strength, with a unit stress, for the great circular compression members, 8 and 12 ft. in diameter, of from 15 680 to 16 800 lb. per sq. in., as shown in Table 24. This was in accordance with Continental practice and with the general recommendations of this Committee, but greatly in advance of the units proposed.

Comparing these sensible unit stresses with those which engineers, at the time, were evolving by the laborious use of the Rankine or Gordon formulas, one can at least begin to see the futility of obtaining a great

NOTE.—Same units for both tension and compression.

variety of compressive unit stresses for the various members of the same structure and each one carried out to practically the last pound with ludicrous accuracy. The almost simultaneous proposing of straight-line formulas by Edwin Thacher, M. Am. Soc. C. E., and by Thomas H. Johnson, M. Am. Soc. C. E., caused a great feeling of relief to bridge designers, but never have they entirely departed from a certain amount of hair-splitting accuracy in the design of compression members, so that now one must rejoice because the Committee has failed to promulgate its new formula, $20\,000 - 100\,\frac{l}{r}$, in favor of flat unit stresses, even though one may not agree with these values.

The effort to establish a "Useful Limit Point" does not, in the writer's opinion, tend toward the desideratum, in that one must fix the unit stresses at the highest possible safe value, when finally all the facts are known. Hence, it would seem advisable to fix the U. L. P. at the point where the record first departs from a straight line, or an absolutely safe value to which unit stresses may more closely approach. Then, again, in purchasing steel for compression members, it would seem to be more logical to specify the tests to be made in compression, to give a certain ultimate compressive strength and the corresponding yield point in compression.

Some valuable light might be thrown upon the variation between thick and thin metal, by testing several pairs of columns, from which $\frac{1}{8}$ in. or so of the hard outer skin had been planed, thus proving to what extent the greater percentage of hard skin in the thin sections was responsible for the higher units.

Mr. Fowler.

The tests of columns of tubes, with and without rivet holes, or rather rivets, recently made by Gustav Lindenthal, M. Am. Soc. C. E., might be profitably amplified in order to decide as to the necessity for deducting rivet holes. The attention of designers is called to Mr. Lindenthal's discussion of this Report in which he proves conclusively the necessity for such deduction, and also to the Committee's tacit acknowledgment of this factor of overstress in rivet lines, by its decision to make the rivet spacing in the test columns closer than is usual in practice, to prevent the buckling of the (over-stressed) material between rivet holes. This is set forth in the first paragraph of page 1592.

Further investigation should include a trip of a sub-committee to Europe, to glean all possible facts of value from Continental practice and to learn their methods of producing a more uniform output of steel.

The future programme of tests should cover, not only columns of the usual types with the usual detailing and the various end conditions, but also the eight forms, or test-size columns approximating them, which are probably the best, from a theoretical viewpoint: the old Phœnix; the old Keystone; the Gray column, with proper details; the ordinary box, and the Lindenthal "double box"; the Forth Bridge cellular circular; the Eads Stave Tube; and the writer's cellular octagonal, as described in his discussion* of the paper by O. H. Ammann, M. Am. Soc. C. E., entitled "The Hell Gate Bridge and Approaches of the New York Connecting Railroad over the East River in New York City." These forms are shown in Fig. 7.

The tests made by the engineers of the Forth Bridge are of interest in this particular connection. Mr. Baker

"tested a piece of ordinary stove pipe, 4 in. in diameter and 2 ft. long, made of sheet iron only about a fortieth of an inch in thickness, and found it stood, without buckling, a compressive stress of 15.9 tons per sq. in.; whereas one of the Britannia Bridge rectangular cells, 18 inches square and 8 ft. long, made of plates and angles half an inch thick, crippled under a stress of 13.6 tons, or say 15 per cent. less stress than that sustained by the piece of stove pipe. If flat plates, as much as half an inch in thickness, behave so badly in a rectangular cell only 18 in. square, it is hardly necessary to speculate as to what would be the case in tubes 12 ft. square, which would be the size required for the Forth girders."

The statements recently made, on high authority, that the rapid depletion of the raw materials for steel making would probably result in such abnormally high prices for steel within the next thirty years as practically to prohibit the construction of great bridges, should cause us to consider very carefully any proposed reduction of unit stresses. The column formula of the American Railway Engineering Associa-

Though engineers, for some years, have been preparing their designs on a factor of safety of practically two on the elastic limit, they must, in the writer's opinion, arrive at definite results or limits, both as to stresses and strength of members, and use an even smaller factor of

Mr. Fowler. safety, after having learned the lessons of efficiency which are being forced upon them.

Mr. Waddell. J. A. L. WADDELL,* M. AM. SOC. C. E. (by letter).—The drastic step taken by the Committee in establishing the intensity of working compressive stress in carbon-steel struts at 12 000 lb. for all values of $\frac{l}{r}$ below 80, and beyond that range reducing it according to the formula,

$$C = 12\,000 - 100\left(\frac{l}{r} - 80\right),$$

up to the limit of $\frac{l}{r} = 120$, does not appear to the writer to be warranted by certain facts.

In the first place, the sections used for testing are small, as compared with those used in bridgework for chord members, although they are more nearly normal for web members. Besides, most of the types of struts tested had open faces, though bridge chords generally have one cover-plate and one laced face. Again, there should have been a series of tests for comparatively small values of $\frac{l}{r}$, because it is hardly conceivable that a short block will not resist compression at least as well as any member made of the same metal will resist tension. In the years long gone by, it was the prevalent opinion that such short struts could be stressed somewhat higher per square inch than the tension members; then custom decreed that the limiting intensities of working stresses should be alike; but now comes a further and most radical cut, amounting to 25 per cent. The Engineering Profession should pause a little before incorporating this innovation into its standard bridge specifications.

Some 14 years ago the writer made twelve tests of struts of both carbon steel and nickel steel, the sectional area thereof being 17.5 sq. in., and the lengths 10 and 30 ft., making the values of $\frac{l}{r} = 27$ and 81, respectively. The results of these tests were published by the Society in 1909 in a paper entitled "Nickel Steel for Bridges",† from which paper it can be seen that the carbon-steel struts gave, as averages, unit elastic limits of 28 800 lb. for the short ones and 16 800 lb. for the long ones, the corresponding unit ultimate strengths being 39 200 and 30 500 lb. It is true that all the struts had hinged ends, hence, to compare the results with those found by the Committee, they should be increased about in the ratio of

$$R = \frac{16\,000 - 60\,\frac{l}{r}}{16\,000 - 80\,\frac{l}{r}}.$$

* New York City.

† *Transactions*, Am. Soc. C. E., Vol. LXIII (1909), p. 101.

Substituting $\frac{l}{r} = 27$ and $\frac{l}{r} = 81$, we have, respectively, 1.04 and 1.17. Mr. Waddell.

Applying these figures, we find, for the elastic limits, 29 950 and 19 660, and, for the ultimate strengths, 40 770 and 35 690.

It is difficult to compare these figures with the averages of those found by the Committee, because it did not determine the elastic limit, but, instead, a new function designated "Useful Limit Point". It is true that the writer's method of determining the elastic limit was arbitrary; but it was conservative. For the value of $\frac{l}{r} = 85$ (which, for comparison, is sufficiently close to the writer's superior limit of 81) the Committee found, as averages, for the "Useful Limit Point" and the ultimate strength, respectively, 27 100 and 30 200. The former possibly might properly be compared with the average of the results obtained by the writer, in the case of the longer columns, for a permanent set of 0.015 in., *viz.*, 21 300, which, of course, as before, must be multiplied by 1.17, making 24 920.

Comparing the ultimate strengths, we have 30 200 lb. per sq. in. found by the Committee, against 35 690 lb. found by the writer. As the quality of the metal was practically the same in both cases, this great difference is presumably due primarily to the fact that the writer's struts were detailed so perfectly that they developed the greatest possible strength from the section, which apparently was not the case in some of the Committee's test struts.

The writer's latest specifications for designing* permit the following intensities of working stresses for carbon-steel columns:

For fixed ends,

$$C = 16\,000 - 60\,\frac{l}{r},$$

and for hinged ends,

$$C = 16\,000 - 80\,\frac{l}{r}.$$

Substituting in the latter 27 and 81 for $\frac{l}{r}$, we have, respectively, 13 840 and 9 520. Comparing these figures with the results of the writer's tests, which gave for the elastic limits 28 800 and 16 800, we find the ratios to be 0.48 and 0.57. As the aim in preparing the formulas was to make the intensity of working stress about one-half of the elastic limit, it is evident that there is an error of 2% on the side of safety for the short columns, and one of 7% on the side of danger for the long columns. It must be remembered, though, that for the latter the writer used a very conservative method in trying to locate the elastic limit.

* "Bridge Engineering", Chapter LXXVIII.

Mr. Waddell.

These experiments by the writer show conclusively the fallacy of using a constant intensity of working stress up to a limit of $\frac{l}{r} = 80$; because (when corrected for fixedness of ends) the elastic limits are 29 950 for $\frac{l}{r} = 27$ and 19 660 for $\frac{l}{r} = 81$. Taking one-half of each of these, we have, for the allowable working intensities, approximately 15 000 and 10 000 lb., though the Committee would use 12 000 lb. for both cases. This shows that the Committee's assumption is illogical. The writer's formula for fixed ends makes these intensities 14 380 and 11 140. Therefore, it does not seem justifiable to stress as high as 12 000 lb. for $\frac{l}{r} = 80$; and it is decidedly uneconomic to use that intensity for $\frac{l}{r} = 20$ or 30, as would be the case in chord sections of many railroad bridges.

In the writer's 42 years' experience, connected mainly with bridges, he cannot recall a single instance of the failure of a properly designed compression member, but he has known of tension members failing, although, truth to tell, not many of them, except in detail. Were it true that we were over-stressing short columns some 35% when using for fixed ends the old standard formula,

$$C = 18\,000 - 70\,\frac{l}{r},$$

there inevitably would have been numerous column failures in old bridges in which the actual intensities of working stress on the tension members approached the danger limit.

As for the great differences in resistance between struts fabricated with thin metal and those fabricated with thick metal, the adoption of more thorough and cooler rolling for the latter would probably reduce that difference materially. In any case, though, we should certainly need more experiments on this point before upsetting fundamentally the standard practice of American bridge engineers.

Mr. Godfrey.

EDWARD GODFREY,* M. AM. SOC. C. E. (by letter).—The Final Report of this Committee contains some very valuable data, and deserves the study of all structural engineers. It has long been evident to thoughtful engineers that columns, as commonly designed, are far from having the alleged factor of safety of four which they are so commonly said to have. It has also been evident that there is no warrant in fact for the unit stress, used in tension members, to be applied also in compression members, even though there is a reduction for slenderness.

* Pittsburgh, Pa.

Mr. Godfrey.

On the face of the results of these tests one striking fact is the small difference between the values for the strength of columns of 50 and 120 radii in length. At first, this would appear to upset formulas and ideas on the relative strengths of short and slender columns. However, correct interpretation of the results brings these tests into harmony with both theory and practice. In other words, correct column theory is not proved to be unreliable, and good practice is not proved to be unsafe; though the fact is that, for indiscriminate designing, a lower unit ought to be used in the column formula.

The three ratios of slenderness used for most of these tests are 50, 85, and 120; but it is not pointed out that these ratios contemplate lengths which are between perfectly fixed ends. It is true that the column formula in general use in America—the straight-line formula—is applied without any reference to the rigidity of the ends; but it is also true that examples of truly fixed-ended columns are so rare as to be considered negligible. Columns which butt squarely on a masonry base are fixed-ended, and correspond, at one end only, to the columns of these tests. Practically all other compression members of any size in structures may be considered either continuous or pin-ended at the ends, but few are really fixed-ended.

The real length of these test columns, considered as pin-ended, that is translated into practice, is just half of that shown in the Committee's report. The ratios of slenderness are then 25, 42.5, and 60, instead of 50, 85, and 120. The significance of this distinction is seen when a line is plotted representing the ordinary straight-line formula and is compared with the Committee's results of tests after correcting them for slenderness ratio.

The writer has deduced* a purely theoretical column formula which, although it is very complex, gives a locus which is almost identical with the straight-line formula in the range of practical column ratios as used in structural work. The one assumption on which the derivation of this formula is based is that the column is imperfect, and that the imperfection exhibits itself in the deviation of the column from a straight line by an amount of $\frac{1}{300}$ of the length. The formula shows the direct load per square inch which will give an extreme fiber stress on the assumed imperfect column of 16 000 lb. per sq. in.; and this load is found to agree, almost exactly, with $16\,000 - 70\,\frac{l}{r}$ up to the ratios of slender columns.

The average elastic limit of short pieces in compression is not far from 32 000 lb. per sq. in., as shown by the Committee's report. If now, the values of the straight-line formula or the writer's formula are doubled (on the assumption that the factor of safety is two), and if the line is plotted on the Committee's Plate XXXVI, correcting the

* In his book, "Steel Designing."

Mr. Godfrey.

ratios of slenderness to just half of those shown, the line will traverse right through the dense portion of that plate, where the greater number of test results lie. Furthermore, the shape of this line agrees pretty closely with the shape of the various lines for the individual column groups. This would not be the case with the false ratios given on Plate XXXVI.

Engineers have long recognized that when the elastic strength of a column has been reached, or has been exceeded by a small amount, it is only a matter of time or the repetition of the same load, until the column fails. The same is true of tension members, though the time and the repetition of stress need to be greater. Chains are commonly used for loads, which give fiber stresses that exceed the elastic limit of the steel; and they commonly fail under the treatment, unless they are annealed in order to restore the weakened metal.

These tests do not give surprising results, nor results out of harmony with theory, when that theory recognizes that a column is an imperfect member and one in which the imperfection intensifies the destructive effect of loading near the elastic limit. A tension member which is bowed will be partly straightened out under high load, and thus the effect of this imperfection, in adding bending strains, is diminished.

The real factor of safety of a tension member subject to a stress of 16 000 lb. per sq. in. is not much greater than two, for the real elastic limit of ordinary structural steel is not much greater than 32 000 lb. per sq. in. The real factor of safety of a compression member having a stress of $16\,000 - 70\,\frac{l}{r}$ per square inch would be about two, with proper design and metal which is properly rolled, that is, worked down enough to refine and harden it. Because of uncertainties of design and of the quality of the material, however, the writer believes that a value lower than 16 000 should be used in the straight-line formula. He believes that $15\,000 - 65\,\frac{l}{r}$ would be a good formula for compression members.

The writer has no apprehension as to the safety of columns designed by the ordinary straight-line formula, when the structures are properly designed, and when they are not overloaded, for he believes that a factor of safety of two is sufficient when the ultimate limit of strength on which this factor is based is an elastic ultimate, and not an ultimate found by speedy loading and rupturing of a member which would fail under much less load if given time.

The Euler load, with a factor of safety of five, is used by European designers. This is an absurdity, for the reason that where the Euler formula has practical application, namely, in slender columns, clearly

Mr. Godfrey.

outside of the range of good structural design, no factor of safety of five is needed. There are long wooden derrick booms, being used every day, which have a factor of safety of less than two, based on the Euler formula. The use of the Euler formula for short columns is worse than a guess. At 60 radii that formula shows an ultimate unit stress of 80 000 lb. The Committee's tests show 19 200 to 31 100. At 25 radii the Euler formula shows an ultimate strength of 460 000 lb. per sq. in. No comparison is needed. What meaning could a factor of safety of five have where the ultimate strength shown in the formula bears no relation whatever to the real ultimate strength of the column? The saving feature of European specifications is the upper limit, which, the writer believes, is about 14 000 lb. per sq. in.

Cause for apprehension, backed by the results of these tests, lies in common methods of design, which frequently ignore eccentric strains, and in the overloading of structures.

The report* of the Committee on Iron and Steel Structures of the American Railway Engineering Association, makes certain recommendations. The report states:

"Unit strains in tension to the extent of 26 000 lb. in structural open-hearth steel and 22 000 lb. in wrought iron will not, in themselves, be sufficient justification for suspending traffic or condemning the structures."

Again it is stated:

"That means if you cut down speeds you can run heavier overloads. It would mean practically taking a 60-ft. girder span at full speed on an overload of about 71 per cent., while at slow speed the overload would be something like 122 per cent."

These ideas are again set forth in Vol. 15 of the *Proceedings* of that Association. It is further stated that "we know from numerous tests and long experience" that properly designed bridges in good condition will safely withstand an overload of 50% without any traffic or speed regulation, and, if speed is regulated, an occasional overload of 100 per cent. Further:

"An E-50 A. R. E. Assoc. Specification bridge is a good and economical type with sufficient strength to carry safely, in regular unrestricted service, the heaviest locomotives that can be safely operated without a possible complete revision of present standard clearances."

Now, the relative impact between low speeds and high speeds is something that nobody knows anything about. Some tests have shown less impact for a high speed than a lower one. Impact is caused by roughness of track and lack of balance of driving wheels. If the compression members of a bridge were loaded from 50 to 100% above the ordinary units, where were the factors of safety?

* *Proceedings*, Am. Ry. Eng. Assoc., Vol. 9.

Mr. Burr. WILLIAM H. BURR,* M. AM. SOC. C. E. (by letter).—The work of the Special Committee on Steel Columns and Struts has extended over a period of 9 years, one progress report having been made about a year after the creation of the Committee. After such a long period of activity, it is only reasonable to suppose that the Committee would have covered much ground in a thorough and conclusive manner, especially in view of the fact that a great testing machine of unusual power and accuracy had been placed at its disposal. It is a little disappointing, therefore, to find that the most used type of cross-section of steel column up to the present time is not included in the scope of the Committee's consideration. These tests have not included any column section in which lattice bars or stay-plates are used for holding the component parts of the column in place so as to make an effective compression member.

It is obviously of real importance to learn by actual test the resisting capacities of columns with spacing details, and also of those which are built up or rolled so that they do not require such spacing details as lattice bars and spacing plates or battens; but, as those of the former class are far more numerous than those of the latter, up to the present time, the work of the Committee would have been much more nearly complete if the investigations had included both classes. Certainly, the element of time was not lacking to accomplish such a result.

All the columns were tested with "flat ends", unquestionably the most uncertain end condition which could be seriously considered for such a purpose. Clearly, if the end bearings could be made mathematically exact and at right angles to the axes of the columns tested, there would be reached the condition of true fixedness, at least at the beginning of the test of each column.

That condition, however, would immediately disappear, and the column would at once become eccentrically loaded—with constantly increasing eccentricity—as the load on the column increased. It will presently be shown that an increasing eccentricity of loading took place in probably every column tested in the entire series. In other words, the series of tests is one of columns eccentrically loaded, and with an eccentricity constantly increasing, and rapidly so after passing the limit of elasticity.

It is essentially impossible to face the ends of a column so as to make a strictly accurate fit at each end. Apparently, this was the case in this investigation, as the Committee states:

"Considerable difficulty has been found in securing bearing blocks of sufficient accuracy, and it was necessary for the Bureau to go over all the blocks and dress them to a surface with a variation of not more than plus or minus 0.001 in."

* New York City.

Mr. Burr.

Again, in the instructions issued by the Committee for testing, there is found the statement: "The ends of the columns shall be dressed flat to reduce the amount of shimming to a minimum." It can scarcely be expected that the shimmed flat end of a column would be in condition to be uniformly compressed, however carefully the shimming might have been done. In fact, it would scarcely be too much to state that any shimming whatever would be practically certain to render centric loading of the column impossible, and the extent of the eccentricity induced would be quite impossible to determine. The report does not contain any satisfactory statement as to the reason for the choice of this uncertain flat-end condition for the investigation. It was recognized among the older investigators that the flat-end condition introduces variables of eccentric bearing at one end which differ from those at the other, with the attendant eccentricity of loading, which cannot be estimated, carrying with it a corresponding amount of extraneous and uncertain bending in the column. This variable eccentricity and bending moment reduces obviously the resisting capacity of a column by an amount quite impossible to determine.

Furthermore, the flat-end column, with a few rare exceptions, is now never used in structures in other shape than columns of cast iron, and columns of this material have nearly disappeared in first-class work. Even in heavy riveted structural joints, the endeavor is essentially universal to make all lines of stress intersect in a point which will insure centric loading; but, even there, the elastic motions of the intersecting members prevent the fixed-end condition. It is for this and other substantial reasons that some engineers have well contended, as the writer believes, that the pin end corresponds more nearly than any other to the general conditions under which structural columns are used; and, hence, that the results of column tests with pin ends may be used safely and properly for practically all structural columns wherever they may be found.

Fortunately, the measurements of the strains at different parts of loaded columns when under test enable the preceding observations to be rather markedly illuminated. The report states that these strains were measured to $\frac{1}{5000}$ in. As such measurements, to be of greatest value, must be as accurate as possible, it is a matter of surprise that a more accurate measuring apparatus was not used, as it is now quite possible to measure, by the aid of a perfect screw, to $\frac{1}{50000}$ in., and by close estimation to less than 0.00001 in. A geared dial is not the most accurate instrument available at the present time, but it may be accepted for the present purpose.

Prior to using the data in the tabular results of the report, it is proper to state that, with this important and rather analytic subject before a committee of engineers for the period of 9 years, it would be reasonable to expect at least the fundamentals of a thorough

Mr. Burr. analytic statement of the typical or principal stresses in a centrically-loaded column, if not supplemented by at least a simple outline treatment for eccentrically-loaded columns. As a matter of fact, there is not in the entire report any matter whatever, either analytic or other, bearing on the stresses found at various points of the cross-section of a loaded column, either at the ends, or at the center, or at any other section. The only intensity of stress given anywhere is the mean or average intensity, which, of course, is the same from one end of a column to the other. All conclusions reached, so far as they depend on any intensity of stress, are expressed in terms of that mean or average. Nor has there apparently been any effort on the part of the Committee to interpret in any way the significance of the varying strains at different parts of the column, although some highly important conclusions may be based on results thus disclosed.

It is sufficient here to observe that, in general, the state of stress in any column, as has long and well been known, is a combination of a uniform stress and a stress couple, as shown in Fig. 8. In that figure, $D\ K = C\ L$ is the uniform intensity of stress on any section, $K\ L$, and is the mean or average intensity shown as "Unit Ultimate Strength", or "Average Ultimate Strength", in Tables 1, 2, etc., of the report. As a matter of fact, however, the actual intensity or compressive stress which determines the failure of the column is the quantity, $H\ L$, of Fig. 8, and the comparatively small intensity or compressive stress, $F\ K$, is found on the opposite side of the section. It can readily be seen from Fig. 8 that, comparatively speaking, the intensity of stress, $C\ L$, may not be of much consequence, inasmuch as the maximum intensity, $H\ L$, actually exists at the same point.

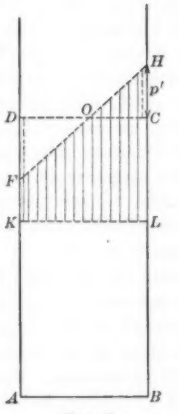

FIG. 8.

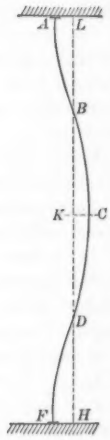

FIG. 9.

Referring to Fig. 9, the full line, $A\ C\ F$, represents the center line of a column with flat ends at A and F, the deflections being much exaggerated. If the ends are accurately flat and at right angles to the axis of the column when unloaded, and if the bearing surfaces are rigidly unyielding, the imposed load, if not too great, will cause the center line of the column to take the reversed curve shown, $B\ L$ being equal to $B\ K$, and similarly for the other half of the column. The deflection, $A\ L$, will also be equal to $K\ C$. Hence, the center deflec-

tion, $K\,C$, will be equal to the eccentricity of loading, $A\,L$. The maximum bending moment in the colmun, at C and at A, will be equal to the column load multiplied by $K\,C$, or the eccentricity, $A\,L$. As a matter of fact, the unavoidable inaccuracies of flat ends and the elastic motions caused by column loading derange to some extent the conditions outlined, although the principal features are, in general, approximately maintained. Bad fitting of the ends, or other influences of a similar kind, may even bring the point of reversed curvature, B, up near to L (Fig. 9), thus approximating the condition of a round end. In the present instance, however, the end fitting was doubtless unusually accurate, producing closely the ideal conditions described. With the increasing load, however, the elastic motion at the ends of a column would cause increased eccentricity, as is actually shown by the increasing measured strains. Mr. Burr.

These matters may be illustrated by taking the data for Test No. 30 first with a total load of 113 600 lb. and then a total load of 284 000 lb. The compressions for the gauged length of 8 in. at the middle of the column are 0.0026 and 0.0026 in., for Points 1 and 3, and 0.0025 and 0.0028 in. for Points 5 and 7; which shows that there was irregularity of deflection, but that there was a vertical deflection. Using 30 000 000 for the modulus of elasticity, with the preceding compressions for 8 in. in length, the intensities of stress are found to be:

For Point 1..... 9 750 lb. per sq. in.
" " 3..... 9 750 " " " "
" " 5..... 9 375 " " " "
" " 7.....10 500 " " " "

These intensities show that the column deflected upward with the load of 113 600 lb., giving the following mean fiber stresses:

At Points 1 and 7.....10 125 lb. per sq. in.
" " 3 " 5..... 9 563 " " " "

562

Hence, in Fig. 8, $p^1 = \frac{562}{2} = 281$ lb. per sq. in.

As the moment of inertia of the cross-section of this column is $I = 64.54$, and as the half depth of the column is 3 in., the moment of the stress couple, indicated in Fig. 8, is

$$M = \frac{p^1 I}{d} = \frac{281 \times 64.54}{3} = 6\,045 \text{ in-lb.}$$

Hence, the eccentricity of the load was $\frac{6\,045}{113\,600} = -0.053$ in.

The negative sign is used to indicate upward deflection.

Mr. Burr. When the load was increased to 284 000 lb., the strains in the gauged 8-in. length were:

At Point 1, 0.0068 in.; hence the intensity of stress = 25 500 lb. per sq. in.

At Point 3, 0.0086 in.; hence the intensity of stress = 32 250 lb. per sq. in.

At Point 5, 0.0078 in.; hence the intensity of stress = 29 250 lb. per sq. in.

At Point 7, 0.0071 in.; hence the intensity of stress = 26 625 lb. per sq. in.

Mean fiber stress at Points 1 and 7. . . .26 063 lb. per. sq. in.
" " " " " 3 " 5. . . .30 750 " " " "

These intensities show that the deflection was downward. Using the foregoing data, the moment of the stress couple is

$$M = \frac{2\,344 \times 64.54}{3} = 50\,419 \text{ in-lb.}$$

The eccentricity of the load was $\frac{50\,419}{284\,000} = +0.18$ in.

Again, the recorded results of Test No. 54, Type 2, may be used in the same way. With a load of 96 600 lb., the strains on a gauged length of 8 in. at mid-length of the column are:

At Point 1, 0.0025 in.; hence the intensity of stress = 9 375 lb. per sq. in.

At Point 3, 0.0023 in.; hence the intensity of stress = 8 625 lb. per sq. in.

At Point 5, 0.0026 in.; hence the intensity of stress = 9 750 lb. per sq. in.

At Point 7, 0.0027 in.; hence the intensity of stress = 10 125 lb. per sq. in.

These results indicate that the deflection is horizontal and to the "south". Taking half the difference of the mean intensities at Points 1 and 3, and 5 and 7:

$$p^1 = \frac{938}{2} = 469 \text{ lb. per sq. in. (Fig. 8).}$$

The moment of inertia of the cross-section is 53.84, the width of the section being 8 in. The moment of the stress couple is then

$$M = \frac{469 \times 53.84}{4} = 6\,313 \text{ in-lb.}$$

The eccentricity of the load, therefore, was $\frac{6\,313}{96\,600} = +0.065$ in.

Finally, with a load of 280 140 lb., the corresponding strains in the gauged length of 8 in. were: Mr. Burr.

At Point 1, 0.0068 in.; hence the intensity of stress = 25 500 lb. per sq. in.
At Point 3, 0.0060 in.; hence the intensity of stress = 22 500 lb. per sq. in.
At Point 5, 0.0105 in.; hence the intensity of stress = 39 375 lb. per sq. in.
At Point 7, 0.0116 in.; hence the intensity of stress = 43 500 lb. per sq. in.

Using half the difference of the two mean intensities at Points 1 and 3, and 5 and 7:

$$p^1 = \frac{17\,438}{2} = 8\,719 \text{ lb. per sq. in.}$$

Hence, the moment, M, of the stress couple is

$$M = 8\,719\,\frac{53.84}{4} = 117\,358 \text{ in-lb.}$$

The eccentricity, then, is $\frac{117\,358}{280\,140} = +\,0.42$ in.

These computations show that the eccentricity of loading increases with the increase of load, and that, even within the elastic limit, in Test No. 54, it was more than 5% of the width of the section. After the elastic limit is passed, the eccentricity increases rapidly, and increases the moment of the stress couple with equal rapidity. This is the explanation of the hastening failure of the column after passing the elastic limit.

The intensities of stress obtained by actual strain measurements demonstrate in a marked manner the gross error likely to be committed in basing analytic conclusions on the mean or average intensity of stress in the cross-section of a loaded column. In the case of Test No. 30, with a total load of 284 000 lb., and with a mean intensity of stress of 25 000 lb. per sq. in. at the mid-length section of the column, the strain measurements show that the mean maximum compression in the same section is 30 750 lb. per sq. in., which is 20% more than the average. The results found in connection with Test No. 54 are still more striking with a total load of 280 140 lb., giving a mean intensity of 29 000 lb. per sq. in. on the mid-length section. The strain measurements disclose a mean maximum intensity of compression of 41 400 lb. per sq. in., an increase of nearly 50% above the mean intensity. This column gave an ultimate resisting capacity of about 30 000 lb. per sq. in. as an average intensity over the entire section, but the strain measurements show that the maximum intensity of compres-

Mr. Burr. sion in the section might have been as high as from 45 000 to 50 000 lb. per sq. in., or even higher.

A large but undeterminable part of this excess of the maximum intensity of compression over the mean is directly due to the eccentricity of the column loading. Even if it is admitted that the strain measurements were not as highly accurate as could be desired—which is probably true—this analysis demonstrates conclusively that the varying and rapidly increasing eccentricity of loading in these tests is far too large an element to be ignored, and that any part of the investigation bearing on, or influenced by, the intensities of compressive stress in the cross-section of the column must take into account, at every step of the operation, the maximum intensity of stress, and not the mean.

The report contains the details of stress measurements of Tests No. 30 and 54 only. If similar details of other tests were printed, doubtless more marked cases even than No. 54 would be found.

The Committee emphasizes the fact that the programme of investigation was arranged so as to eliminate as far as practicable "all variables except that of form". The meaning of this statement is not quite clear. It certainly could not have been the intention of the Committee to eliminate the ratio, $\frac{l}{r}$, for it has been given a variation from 50 to 120, and value would have been added to the results of the tests if other ratios than the three selected had been used. Again, it has been seen that the eccentricity of loading involved was highly variable. The carbon content was also varied. Unfortunately for the designers of structural steel columns, as has already been observed, it was decided to eliminate from the columns tested such spacing pieces as lattice bars, tie-plates, and similar details. Details of this kind have been used so widely in the past, and are still likely to be much used, that full-size tests determining their value and dimensions would be highly important in steel structural design, even at the present time.

It has been a fundamental principle in the best design of cross-section for a steel column to distribute the metal so as to make each of the different parts individually self-supporting, as far as practicable, and mutually supporting as parts of a whole, so as to maintain the full value of the radius of gyration in the direction of bending, up to the instant of actual failure. Convenience of construction, accessibility for painting, and other matters of a similar nature do not permit a perfect application of such fundamental considerations, but they do influence design strongly. The Phœnix column probably fulfilled these ideal conditions more nearly than any other section ever devised, but the inaccessibility of the interior of the column, and

difficulties in detailing, would prevent any such section from coming into general structural use. Mr. Burr.

The value of this investigation would have been much enhanced if its scope had been sufficiently increased to throw the light of actual test results on the relative value of a number of forms of cross-section which, in the past, have been much used, and are still. The type of section used almost entirely by the Committee, namely, with the individual projecting flat and unsupported parts, is the least effective of all for purely column purposes, although, in one shape or another, it is widely used, and the results are correspondingly valuable.

The data obtained by the tests and shown in the tables of the report are highly interesting. The long and well-known decrease of carrying capacity due to heavy sections—that is, those of thick metal—stands out prominently, although in some instances it is masked by the varying content of carbon, as the Committee allowed "the mill to change the carbon content so as to endeavor to produce the same strength for the light material as for the heavy". This attempt to cure the influence of lack of work between the rolls by chasing it with a varying carbon content proved ineffective, as was to be expected. By retaining the same carbon content, a well-determined effect of insufficient work would have been obtained.

It is greatly to be regretted that the report did not include a graphical representation of the ultimate resistances, so as to show at a glance the actual relation existing between them and the column ratio, $\frac{l}{r}$. It is true that a more satisfactory probable curve could be drawn with additional results for the intermediate ratios, 68 and 138, as well as for the smaller value, 35. On Fig. 10 are shown the three main groups of tests, as well as the smaller group for which $\frac{l}{r} = 155$, and the single test for which that ratio is 20. Each of these groups actually shows considerable variation, but not more than is to be expected under the condition of flat ends, with the varying eccentricity of the increasing loading, the added influence of thickness of section, and the varying content of carbon. The extra heavy section of Type *5B* gives strikingly low ultimate resistances, lower indeed than one would expect, even with as much thickness of metal as 1¼ in. The content of carbon may have been an important element in this case, but it does not appear to be given in the report. In any event, however, no experienced engineer would permit as high working resistances in columns having excessively thick parts as in those of lighter section.

The value of this graphical representation is that it shows at a glance, among other things, that the working stresses prescribed for columns with end conditions such as those used in this investigation

Mr. Burr. should vary reasonably, not only with the column ratio, but also with other elements, such as the carbon content and the thickness of metal in the different parts of the column section, although too much importance should not be attached to this latter feature unless the thickness is sufficient to decrease markedly the work done between the rolls. If the carbon content is to be varied so as to cure insufficiency of work in rolling, careful tests should be made to determine the desired content with reasonable accuracy, so as to bring the resisting capacity of the column up to the required amount. In every feasible case, however, the needed amount of work should be prescribed and secured.

In order to make a comparison with some of the best of the older tests, there are shown on Fig. 10 the results of the tests of medium-steel angles with flat ends made by the late James Christie,* M. Am. Soc. C. E. It would have added much, both to the interest and value of this report, if the older tests of wrought-iron and steel columns had been shown in comparison with those of the present steel flat-end columns, wherever they were made by reputable experimenters. It is a mistake to assume that the best of those older tests were not sufficiently accurate to be compared with these modern results. Although it is true that the older machines were not as extremely accurate in some respects as the machine used in this series of tests, in some other respects they were at no disadvantage, and the results obtained may be accepted as essentially correct. Indeed, the tests of flat-end angles made by Mr. Christie, taken in connection with others made by him at the same time, probably constitute the most interesting, and in some respects the most valuable, of all structural tests that have ever been made. His papers constitute an almost unrecognized classic in the literature of testing materials. He was, in the best sense of the word, a perfect mechanic. His intuitive sense of the fitness of details and character of appliances to secure desired—and in many cases delicate—results has seldom been equalled by any experimenter in structural materials, and his interpretation of results showed him to be, not only an engineer, but an engineer physicist.

It will be noticed that Mr. Christie's unit results are materially higher than those obtained by the Committee, up to the column ratio of 120, and practically the same at the column ratio of 155. This is doubtless largely due to the fact that he experimented with single angles, and the Committee with built-up sections. With the lower values of $\frac{l}{r}$, the riveting of a built-up section is an element of weakness, as the parts are not held rigidly in position in relation to each other, and, consequently, a slight though quite imperceptible relative motion will correspondingly reduce the unit carrying capacity. It is

* *Transactions*, Am. Soc. C. E., Vol. XIII (1884), pp. 253 and 285.

also partly due to the fact that more accurate flat-end fitting can be made with the smaller single-member angle struts than with the full-size columns used by the Committee. The weakening effect of the increasing eccentricity with the increasing load in the latter would be relatively greater than in the case of the single angles. Mr. Burr.

The angles tested by Mr. Christie were of mild steel, with a carbon content of 0.11 to 0.15, which is distinctly less than that found in the material used by the Committee. It may be properly observed, of course, that results obtained from the small sections of single angles are scarcely comparable with those from full-size columns. Although that is true, the comparison is legitimate, however, for it is at least illuminating as to the general features of the results.

In the older wrought-iron and steel column tests such graphical representations were always accurately made and carefully studied, enhancing greatly the value of those investigations and forming the only reliable basis for the convenient determination of the empirical quantities used both in Gordon's and the straight-line formulas. In the present instance such a graphical representation of results gives a much clearer and more complete view of the different resisting capacities for light and extremely heavy sections than is possible by any tabular statement; and other features are brought out with similar definition. A mean-resistance curve may be drawn through the mean points of the stress groups to represent the straight-line formula within the limits of the tests, or two such mean-resistance lines may be drawn, one through the mean points for the light sections and another through the mean points for the heavy sections.

In scrutinizing such an important report, it is natural to look for evidences of material advancement in the knowledge of the subject investigated. The principal, if not the only markedly original, feature disclosed in the report is what the Committee calls the "Useful Limit Point". When a new scientific term is introduced into any field of research, it generally indicates some important physical feature or discovery corresponding to some new state or quality of the material under test, like the elastic limit or yield point in the field of testing materials. The "Useful Limit Point", however, is not a term corresponding to or signifying any new feature or quality of the material at any particular intensity of loading; in fact, it does not indicate anything whatever regarding the condition of the material in the column under test, except that it must be "somewhere" above the yield point. It is simply an arbitrary term applied to an arbitrarily chosen point on the envelope of the stress-strain curves of the column. It is a point determined by a tangent having a completely arbitrarily chosen inclination, that is, half that of "the last run-up line."*

* The literary elegance of some modern scientific terms or definitions is indeed striking.

Mr. Burr. It is unfortunate, to say the least, that the Committee should have introduced a superfluous term where simplicity is needed. It is difficult to realize why this specially arbitrary and substantially meaningless term can be supposed to acquire such value as the report accords it. It varies greatly, as does the yield point and ultimate resistance, as indeed it is bound to by the nature of the case. It has to be established by the construction of an envelope for stress-strain curves, both above the yield point and below the elastic limit. It has no definite relation to either the yield point or the ultimate resistance. In fact, it is not an exaggeration to say that it has no physical value whatever. As a matter of fact, the yield point may be located just as accurately, if not more so, and has the material advantage of meaning something in the column test.

A feature which will probably challenge some criticism is that part of the report in which is considered the safe working stress for columns "conservative enough to cover the wide range in the results shown by the Committee's programme." Inasmuch as "the usual working stress in tension is approximately one-half the elastic value of the metal", the Committee arbitrarily assumes that "columns should have a safety factor of at least two, based on the U. L. P., in order to be on a parity with tension members." It certainly is not entirely clear why a safety factor of two, based on "the elastic value of the metal" in tension, is on a parity with the safety factor of two in columns based on the Useful Limit Point. Assuming that "the elastic value of the metal" means the elastic limit, there is no conclusive reason whatever for assuming that one-half the elastic limit in tension gives the same factor of safety as one-half the Useful Limit Point of a column in compression. In fact, the two things are radically different, when considered either in reference to the degree of safety in loading or as to the physical condition of the material.

The Committee then takes the average of all the Useful Limit Points of the column tests for the column ratios, 50 and 85. It then takes a mean between that average and the lowest observed value, which gives 23 450 lb. per sq. in. This value is then called 24 000 lb., and the factor of two is applied to it, giving 12 000 lb. per sq. in. for a sort of unit or base working value, which the Committee recommends, it being assumed that static loads only have been considered, "and that a percentage of the static stress will be added to cover the impact due to moving loads."

The averaging of the aggregate test results, for the column ratios of 50 and 85, without regard to the variation of that ratio, and then the averaging of that average with the lowest result obtained with excessive thickness of metal is so crude and irrational as to be entirely

Mr. Burr.

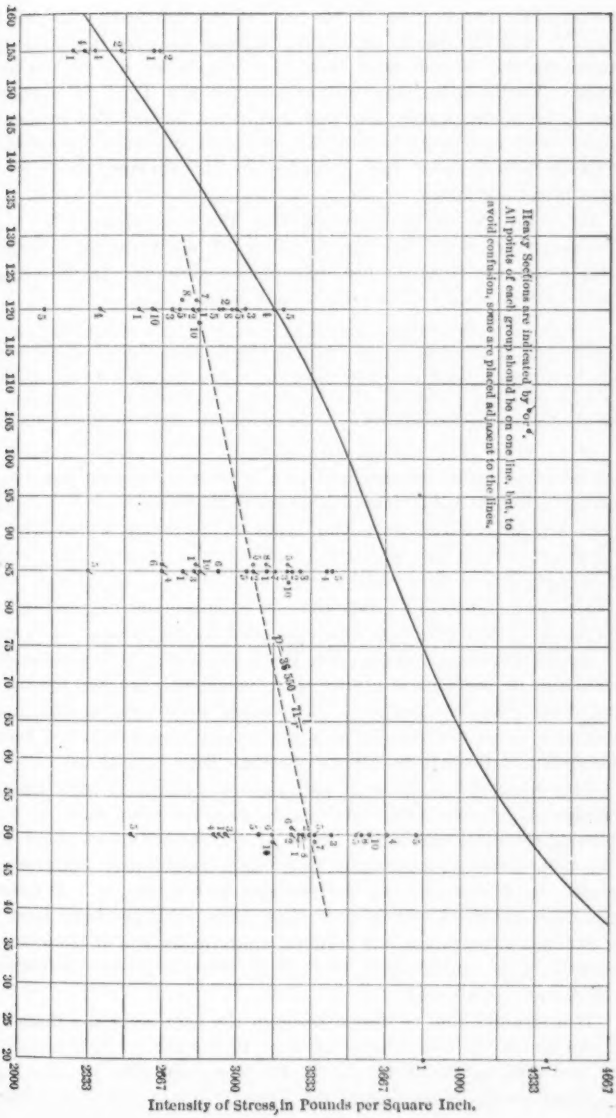

FIG. 10.

Mr. Burr. indefensible, irrespective of the use of the arbitrary "Useful Limit Point". Fig. 10 shows that the decrease of carrying capacity, in increasing the column ratio from 50 to 85, is too material to be neglected. Furthermore, the test results for the Type 5*B* section are seen to be phenomenally low, and should not be included in the determination of a general formula or resistance curve. Any experienced engineer would make due allowance in his working stress for such extra heavy sections.

It is greatly to be regretted that the Committee takes such a hopeless view as to the practicability of determining a reasonable column formula from the tests of full-size columns. In the paragraph at the bottom of page 1630 occurs the following statement:

"Numerous theoretical formulas have been promulgated from time to time, all of them based on entirely elastic material of uniform grade. At the present time it seems useless to the Committee to attempt to write a rational column formula, from a theoretical standpoint, with the possibility of variations of 28% in the strength of the material."

It is true that enthusiastic analysts have proposed from time to time some rather extreme and usually extremely complicated column formulas, but probably few if any experienced engineers have regarded them seriously. The only two types of formulas which have been widely used are the so-called Gordon's and straight-line formulas. It is certainly a fact that Gordon's formula is established from a "theoretical standpoint", but that is equally true of probably nine-tenths of all the practical formulas used by engineers. It is true of all beam formulas, which, like Gordon's, are fitted with empirical quantities or coefficients giving them sufficient accuracy for the most important practical purposes. It is not necessary, in this case, to write a column formula from a theoretical standpoint, but from the standpoint of these tests; otherwise, what value have they?

The straight-line formula was not established from a theoretical standpoint. It was first obtained by plotting the results of tests of full-size columns within the limits of column ratios of about 40 and 120, then drawing a straight line which would best represent those results, in the process of determining the corresponding numerical quantities required. It is true that some attempts have been made to establish the straight-line formula analytically, but it is an empirical formula, pure and simple; and all such attempts are defective and without analytic merit.

If a straight line be drawn through the centers of the three groups of the results of tests shown on Fig. 10 for the column ratios of 50, 85, and 120, as shown by the broken line, ignoring for the moment the three results belonging to the Type *B* cross-section, that line may

be represented by the following equation, p representing the average ultimate resistance, in pounds per square inch: Mr. Burr.

$$p = 36\,550 - 71\,\frac{l}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

This equation holds true for all values of the column ratio between 50 and 120; indeed, it may be taken as essentially correct between 40 and 130.

This formula represents fairly the mean ultimate resistances for the different columns tested. There is a not-well-defined zone of rapid distortion of each column immediately below the ultimate resistance, which cannot be considered as of much resisting value, although the load is constantly increasing, up to the point of failure. By examining the diagrams published in the report, this zone may be taken (for illustration) at about 15%, as an average, of the ultimate resistances. Then, if 85% of Equation (1) for p is taken, and if one-half of that value is considered a safe working stress, which is reasonable, the formula for that working stress will become

$$p = 15\,500 - 30\,\frac{l}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

If the column ratio is 50, the working stress becomes 14 000 lb. per sq. in.; or, if the column ratios are 85 and 120, respectively, the working stresses become 12 950 and 11 900 lb. per sq. in., respectively. These values are certainly reasonable and safe; in fact, it may be said that they are rather below than above the limit of safe values. They are not given here, however, as values that should be adopted, but as illustrating the proper method of procedure to determine safe working stresses. They show that 12 000 lb. per sq. in. is not justified by these tests; and they show, further, that it is irrational and also unjustifiable to take the same unit working resistance for column ratios of 50 and 85. Finally, they certainly show, also, that it is far from useless for the Committee to attempt to write a rational column formula, either from a theoretical, or from some other, standpoint, well adapted to the purpose. If, however, it is not thought desirable to write a rational column formula from a "theoretical standpoint", the preceding operation demonstrates conclusively the possibility of writing such a formula entirely from an empirical standpoint, by the use of these test results.

A variation of even 28% in the ultimate tensile resistance of the material has no essential bearing on this point. A proper formula will represent a general run of material, and, as has been pointed out already, it is a simple matter to adjust or modify the formula for extreme cases of any kind. Indeed, there is no better way of doing this than by the aid of a formula based on the tests of columns in which the variations are found.

Mr. von Fabrice.

R. VON FABRICE,* ESQ. (by letter).—The report of the Special Committee on Steel Columns and Struts is based on results obtained from a series of 213 tests made by the Bureau of Standards at Washington. The tests include only columns with square ends and having sections designed to avoid the necessity of lattices or battens. From the results obtained, the Committee recommends a maximum working unit stress of 12 000 lb. per sq. in. of section on all solid columns with square ends, with $\frac{l}{r} = 80$, or less, and a reduction of the unit stress per square inch, by a straight-line law, from 12 000 lb. per sq. in. for $\frac{l}{r} = 80$, to 8 000 lb. per sq. in. for $\frac{l}{r} = 120$. It must be remembered that this recommendation is only for static loads; special percentage and other allowances in loading must be made for impact and rolling loads.

No account is taken of the following unknown factors which are ever present in all kinds of structures:

Material:

(*a*)—Quality of steel.—High and low carbon.—Amount of work received.

(*b*)—Uniformity.—Segregations.—Hard and soft spots.

(*c*)—Workmanship.—Initial bends.—Inadequate or poor riveting.

Condition of Loading:

(*a*)—End bearing.—Pin or square ends.—Ends not milled perpendicular to axis.

(*b*)—Eccentricity.—Load not applied at axis of column.

(*c*)—Transverse loading.—Combined beam and column action.

(*d*)—Repeated stresses.—Loads repeated and perhaps alternated many times.

Use:

(*a*)—Overloading.—Impossibility of always determining exact loading.

(*b*)—Secondary stresses.—Sometimes a considerable proportion of the primary stress.

(*c*)—Deterioration or corrosion.—Exposure to corrosive elements.

(*d*)—Facilities for inspection.—Forms of columns which may be frequently and easily examined.

Fig. 11 shows the relation between various column formulas and that recommended in the report. It also shows the great reduction in unit loading as recommended by the Committee for values of

* Chf. Draftsman, Public Service Elec. Co., Newark, N. J.

$\frac{l}{r} = 80$, or less, and its relation to other formulas previously used for column design. Mr. von Fabrice.

The maximum value of 12 000 lb. per sq. in. of cross-section, based on tests made only for solid sections of perfect fabrication, workmanship, and extremely small variations in chemical and physical requirements, seems ultra-conservative, especially as practically all previously erected structures have been designed with values as high as 14 000 to 16 000 lb. per sq. in. as a maximum, as column failures are practically non-existent, and as there are no records available of failures of columns which were properly designed according to previously accepted formulas.

Practical experience on existing structures shows defective workmanship, such as defects in bearing, riveting, and alignment, and it is very doubtful whether a column has ever been put in place with every rivet tight and filling out the hole, without kinks or twists, with perfect alignment, uniform in material, and with 100% bearing contact at the splices.

The tests conducted by the Committee do not include latticed sections. Eccentric loading and transverse loading, which tend to reduce the strength of the structure, or increase its cost in proportion to the decrease in allowable stresses in the materials, have not been investigated.

The materials and workmanship as specified for the columns tested were far above normal. The inspection as to materials and workmanship was also more rigid, and the most careful selection of quality of specimen, that is, uniformity of metal, was obtained, which is far from practical conditions. The sections tested were over-riveted throughout, that is, a maximum riveting spacing of 4 diameters of rivet was used. The bearing surfaces were scraped so as to be as nearly perfect as possible, insuring uniform bearing throughout, a condition never obtained in practice. All computations for area of section were made by calibration, and not, as in practice, for nominal area, which amounted to as much as 4% from the nominal area.

The Committee established a working limit for the steel, which it termed the Useful Limit Point. This Useful Limit Point is taken to represent the point where the metal ceases to have positive structural value, and is somewhat below the ultimate unit strength of the material and slightly above the region of perfect elasticity.

The results of the tests made for Columns 5 and 5*B* are very interesting, as they show that the commonly held opinions that the failure of columns is due to the crippling of the outstanding legs, and that an angle $\frac{1}{2}$ in. thick would be more than twice as strong as one $\frac{1}{4}$ in. thick, are erroneous.

Mr. von Fabrice.

The tests on Column 5 were for 8-in. H-columns of 32 lb. per ft., having an area of 9.17 sq. in., and that for Column 5*B* was on 8-in. H-columns of 91 lb. per ft., with an area of 26.64 sq. in. The average Useful Limit Point for the first three tests of Column 5, light section, was found to be 34 700 lb. per sq. in.; for the second, Column 5*B*, it was, for the first three tests, 19 700 lb. per sq. in., or a variation of 15 000 lb. per sq. in. between the light and heavy sections, or, in other words, the heavy sections were found to be only 57% as good, per unit of area, as the lighter sections.

This variation in unit strength is accounted for by the Committee as follows:

"The physical characteristics and strength of structural steel are affected by the amount of working which it receives in passing through the rolls, and, for the same size of ingot, the heavy material does not receive as much working as the light; consequently, for the same chemical composition, the heavier section is weaker."

This, however, was thought by the Committee to have been overcome by changing the carbon content at the mill.

If this is true, then the variation of the Useful Limit Point for Columns 5 and 5*B* shows that great variations in the strength of materials are prevalent, as all the materials used were selected from supposedly the best that the mills could produce as to uniformity of product. Such being the case, it is evident that the present process of manufacture of steel is not what it should be, and that the mills do not produce uniform metal. This would be complicated further by the fact that the present accepted commercial methods of testing do not show such variations, and, therefore, do not give correct indications as to the behavior of the steel under compressive loads. The tests at the mill indicated no such possible variation, because all the materials accepted by the Committee were practically within the limits of the specifications adopted by it, which were identical with the ordinary 60 000-lb. bridge steel, excepting that greater uniformity was required in both chemical and physical qualities.

The difference in strength of Columns 5 and 5*B* is more probably due to the fact that the distribution of the metal in the lighter H-section is better than in the heavy H-section, in relation to the neutral zones of the sections. This is contrary to the explanation given by the Committee. In built-up sections, the increase in metal is farther from the neutral zones than in H-sections, for the increase in weight and, consequently, the distribution of metal is in favor of the lighter column sections. If this were not the case, the box column and other sections tested should show results similar to those for Columns 5 and 5*B* for their respective light and heavy sections. Therefore, the explanation of the Committee for the behavior of Columns 5 and 5*B*, as previously mentioned, is not correct, because the strength and

Mr. von Fabrice.

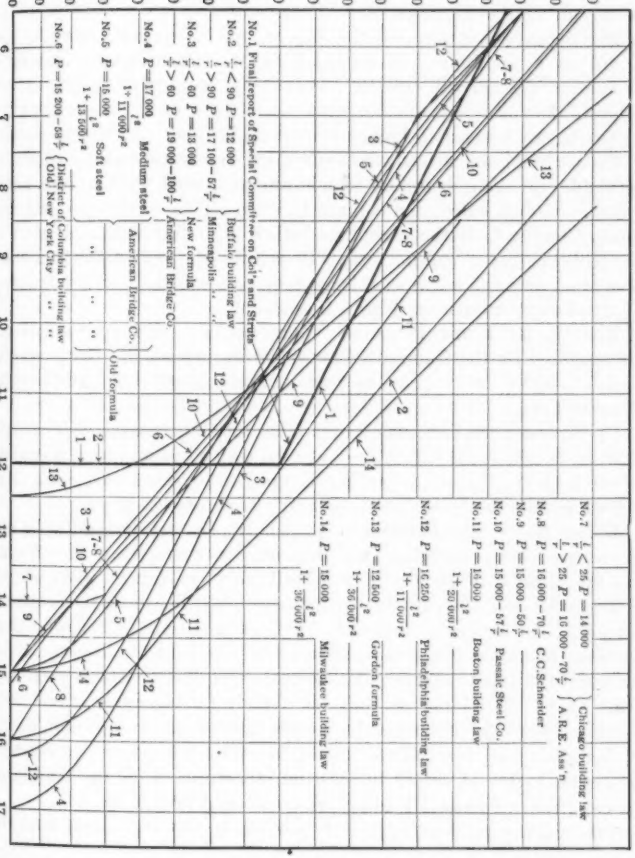

FIG. 11.

Mr. von Fabrice.

uniformity of the steel for the other heavy built-up sections are likewise influenced by the amount of working that the metal receives in passing through the rolls and, therefore, should show results similar to those for Columns 5 and 5*B*.

The report of the Special Committee does not recommend economy either in labor or material, nor does it suggest any means of improving the design of the columns.

The recommendations of the Committee, of using 12 000 lb. per sq. in. as a maximum, if accepted by the Profession as standard for column design, will tend to increase the costs of all construction; and this does not seem to be justified, in view of the great quantity of existing work based on higher stresses and giving satisfactory results.

To use the lower stresses recommended by the Committee might be justifiable for long columns which are subjected to the full 100% of the maximum calculated column loading. This condition of column loading, however, is the exception rather than the rule, and, as it is doubtful whether a column ever will receive the maximum load from all sources at any one time, a large factor of safety (partly unknown) is introduced automatically into the design.

The Useful Limit Point for square-ended, solid-section columns was specified by the Committee at 24 000 lb. per sq. in., therefore, the use of 12 000 lb. per sq. in. as a maximum will give an actual safety factor of two.

Previous column formulas, based on an ultimate compressive strength of from 60 000 to 64 000 lb. per sq. in., and allowing from 15 000 to 16 000 lb. per sq. in. as a maximum, did not permit a factor of safety of four within the "positive structural" value of the steel.

Using the value, 12 000 lb. per sq. in., as recommended by the Committee, and conceding the fact of its correctness, the former maximum stress of 16 000 lb. was really 75% of the reliable strength of the structure, allowing in reality only 8 000 lb., or 50% for safety, instead of, as formerly assumed, 300% of additional strength. Considering the actual practical variations in workmanship, bearing, riveting, etc., it is fair to assume that, for columns designed for a maximum stress of 16 000 lb. per sq. in., the remaining allowable actual 50% is easily absorbed; therefore, the former stresses used in column design do not give any theoretically available actual factor of safety, and the actual factor of safety in existing structures is obtained solely by the condition of partial loading, as mentioned previously.

The limiting value of 12 000 lb. per sq. in. for maximum stress, for columns with ratios of $\frac{l}{r} = 80$, or less, is not verified or justified by observations on existing structures which were designed for higher values; therefore, the Committee's recommendation does not confirm the experiences of actual practice.

From the report the following deductions can be made: Mr. von Fabrice.

1. That the present commercial, physical, and chemical tests are unreliable for correct indications as to the behavior of metal under practical loading, where used as columns or struts.

2. That the present process of manufacture of steel does not produce metal which is of uniform strength, even though the present commercial tests would indicate it to be of such strength.

3. That heavy sections are weaker per unit of area than those of thinner metal.

4. That the actual excess strength in existing structures is nearer 50% than 300%, as formerly assumed, or a factor of safety of one-half instead of four.

5. That the statement: "the form of section has no material influence on the strength of the column", is disproved by tests on Column 5 and 5*B* only.

6. That bulb angles in columns are no stronger than plain angles of equal section.

7. That the unit stresses as formerly used are excessive, and in no case should a greater loading than 12 000 lb. per sq. in. be used.

8. That the statement: "Ratio of thickness to width of outstanding flanges is not the controlling feature for strength of a column", is disproved by Columns 5 and 5*B* only.

9. That the physical characteristics and strength of structural steel are uncertain quantities (if the Committee's explanation for behavior of Columns 5 and 5*B* is accepted). Other tests show only slight variation.

10. That the recommendations were based on the tests made under the most favorable conditions as to workmanship and material, conditions which do not obtain in practice.

11. That the former safety factor of four, as applied to the ultimate tensile strength, is equivalent to a factor of about two, based on the yield point.

12. That, if the columns are to be as strong as tension members, they must be designed with a factor of safety of two, on a basis of Useful Limit Point.

13. That some basis of specifying the amount of working that the metal should receive per unit of volume, in its transformation from ingot to finished shape, should be devised.

14. That the Useful Limit Point of steel, as established by the Committee, gives a more tangible or serviceable indication of the ultimate behavior of the metal, and bears a definite and fairly constant relation between the results of the final and specimen tests.

L. J. MENSCH,* M. AM. SOC. C. E. (by letter).—The Committee has presented to the Society the most elaborate series of tests on Mr. Mensch.

* Chicago, Ill.

Mr. Mensch.

flat-ended steel columns which were ever made. It is quite a disappointment that these modern tests, made under extremely favorable conditions, often did not show up better than, and sometimes not as well as, the tests on pin-ended iron columns, made by the Watertown Arsenal more than 30 years ago. Under these circumstances, one could not expect the Committee to recommend an increase in the customary working stresses—desirable as this would have been in these times of increasing cost of all construction work.

The Committee has pointed out that, with respect to the transmission of the loads at its ends, the practical column is loaded under conditions differing widely from those of scraped ends in the testing machine.

The writer is really surprised that, during the progress of the tests, no attempt was made to test one column out of three with ends as they came from the bridge works; if this had been done for the slenderness ratios of 120 and 155, the Committee would have found the proper justification for its ruling to allow a working stress of 8 000 lb. per sq. in. for $\frac{l}{r} = 120$, which is a drop of 33% below the working stress of a column of $\frac{l}{r} = 80$; this, at first glance, would lead one to believe that the ruling is not in accordance with the tests, which showed a drop in strength of only 10% for columns having a slenderness ratio of $\frac{l}{r} = 120$ below the ultimate strengths of columns of $\frac{l}{r} = 85$.

Long columns with imperfect flat ends behave mostly like columns with frictionless pins, but short columns behave like eccentrically-loaded columns. This fact was impressed on the writer by his experience with wooden struts in reinforced concrete form work, and was clearly proved to him during a visit to the Pittsburgh Laboratory of the Bureau of Standards. Mr. P. H. Bates, in charge of the Laboratory, had the kindness to make the following test, in the presence of W. K. Hatt, M. Am. Soc. C. E., and the writer: A sound piece of 2 by 4-in. spruce scantling, 12 ft. long, stored under shelter for many months, was cut off by hand to a length of 6 ft. and placed in the 600 000-lb. machine, between wedges at the bottom and a piece of timber at the top. The maximum load was 4 000 lb., and the deflection about 2 in. The actual dimensions of the strut were only $1\frac{3}{4}$ by $3\frac{5}{8}$ in., hence the ultimate strength was 630 lb. per sq. in. According to the Watertown Arsenal reports for 1884, square-ended struts of green, white pine, of the same slenderness ratio as the spruce strut, failed at 1 700 lb. per sq. in. The two values of 630 and 1 700 show the difference in strength of the practical wooden column and the

column with perfectly square ends in a testing machine. Here is the explanation as to why the standard textbooks advise the use of a factor of safety of from 6 to 10 for wooden columns. Such high factors of safety have properly been nicknamed "factors of ignorance." Mr Mensch.

Iron or steel columns with ideal pin ends and ideal flat ends do not show such a large difference in strength for the slenderness ratios in practical use, but the Committee did not instruct us in this respect. It realized the demand of engineers for a rational column theory, yet, on account of the non-uniformity of commercial grades of steel, and the great influence of the amount of rolling the various sections receive and the resulting difference in the strength of the columns, deemed it advisable not to attempt the task.

Although there was a great difference in strength in light, medium, and heavy-weight sections, the drop in strength in each type, from the comparatively short column having slenderness ratios of $\frac{l}{r} = 50$ to $\frac{l}{r} = 155$, was remarkably uniform, and it is this decrease of strength which engineers want to have explained, it being known for many years that the grade of steel and the amount of rolling greatly affect its strength, and it being quite common practice, in reinforced concrete, for example, to allow a higher stress on wires than on bars from which the wires are made.

This deficiency in the report of the Committee the writer will endeavor to supply. A solution of the problem cannot be found by adhering to the common theory of flexure as propounded in the textbooks in the stereotyped form:

1 The modulus of elasticity is constant;
2 A plane section before bending remains plane after bending;
3 The direct stresses vary uniformly across the section in all cases (Hooke's law);
4 Calculations are made with references to working stresses and safe loads, rather than with references to ultimate stresses and ultimate loads.

One does not know what "proper working stresses" are, unless one makes tests to destruction or undue distortion; therefore, Point 4 leads only to much speculation and many exercises in mathematics, without being conducive to an exact understanding of the strength of materials.

Point 1 has been disproved by all careful observers, and by Figs. 5 and 6 and Plate XXXIII of the Committee's report.

Point 2 is disproved by Plates XXXI and XXXII, and was never proved by anybody for high stresses.

Mr. Mensch.

Hooke's law is acknowledged to be only an approximation for steel at low stresses, is certainly far from being correct for high stresses, and is never true for concrete, wood, or cast iron, for any stage of loading.

A correct solution of the beam or column theory can only be found by examining the conditions at the time of failure or just before it.

For this condition the writer makes the following assumption: A column fails when, in any cross-section, the extreme fibers on one side of a cross-section are stressed beyond the yield point and are subjected to a strain which is from 50 to 100% greater than the deformation just below the yield point. Following the lead of the Committee, this maximum strain will be called the Useful Limit Strain (U. L. S.), and the corresponding stress the Useful Limit Point (U. L. P.), which stress is not identical, however, with the point adopted by the Committee.

The Committee did not furnish stress-strain diagrams for the separate angles, plates, or beams, but only for the built-up columns up to failure, which diagrams are somewhat clouded by the influence of the rivet holes and the bending of the columns. Figs. 5 and 6 and Plate XXXIII show such diagrams, and they can be compared in shape to cubic (or higher) parabolas. Even with the not strictly correct assumption of a plane cross-section remaining plane after deformation, one can readily see that, in any cross-section of a bent column, where the extreme fibers are strained to the U. L. S., the fibers which are quite distant from them, although strained quite considerably less, are subjected to stresses only slightly less than the U. L. P., and very much more than the old straight-line theory would warrant us to assume.

The second assumption, then, is, that a column fails when, in any cross-section, the extreme fibers on one side are stressed to the U. L. P.; and the distribution of the unit stresses over the section follows the law of a cubic parabola. The cubic parabola was adopted because it gave a good and sufficient agreement with tests, and is simpler in application than any higher curve. Fig. 12 shows the outline of such a parabola.

Let f_c represent the rise of the parabola and the U. L. P.;
" kd represent the semi-chord and the distance of the neutral axis from the extreme fiber in compression;

then the equation of the parabola is $y^3 = \frac{(kd)^3}{f_c} x$

or $x = \frac{y^3}{k^3 d^3} f_c$ ..... (1)

or the stress, f^y, at any point, y, equals $f_c - x = f_c \left(1 - \frac{y^3}{k^3 d^3}\right)$ .. (2)

Mr. Mensch.

The area, OAB, represents the sum of all stresses between the neutral axis and the extreme fibers, and equals $\frac{3}{4}\ b\ kd\ f_c$ .....(3) when the width of the section is constant and equals b.

The area, $OCA = \frac{1}{4}\ b\ kd\ f_c$ .....(4)

The distance of the centroid of OAB from $OB = 0.4\ kd$. (5)

" " " " " " OCA " " $= 0.8\ kd$. (6)

The tangent at A intersects the x axis at $2\ f_c$ from O.

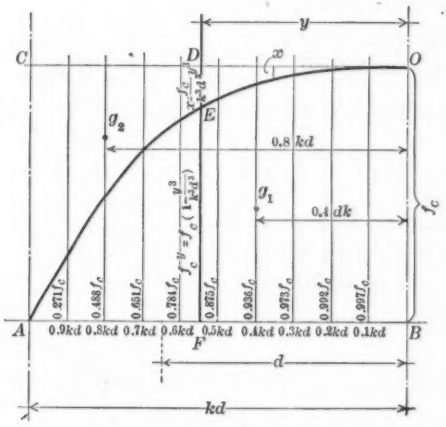

FIG. 12.

The writer developed the theory of long columns by first solving the problems of the short eccentrically-loaded column. After he found a substantial agreement between his theory of eccentrically-loaded columns with actual tests to destruction, he found a simple method to determine the sidewise deflection under which long columns fail, and considered a long column at the moment of failure as a short column with a known eccentricity.

Fig. 13 illustrates short, eccentrically-loaded columns. Where the entire cross-section of the column is in compression, as shown in Fig. 13 (a), the neutral axis is outside of the cross-section, and the value of k is greater than 1.

By increasing the eccentricity we may reach a case where the neutral axis coincides with one edge of the section, such as shown in Fig. 13 (b). Here k equals 1.

Mr. Mensch.

For larger eccentricities, the neutral axis will fall inside of the section, as shown in Fig. 13 (*c*), and k becomes smaller than 1.

For a rectangular cross-section, it is a very simple matter to find a relation between the ultimate load, its eccentricity, the dimensions of the cross-section, and the U. L. P.

For Fig. 13 (*a*) we easily find that the sum of all stresses,

$$W = b \times \text{area } OBDF - b \times \text{area } OED,$$

$$\text{or} \quad W = b \times d\, f_c - b \times \frac{1}{4} d \times f_c \times \frac{1}{k^3} = b\, d\, f_c \left(1 - \frac{1}{4\, k^3}\right). \quad (7)$$

The moment of the load, W, about the extreme fibers in compression,

$$M = b \times \text{area } OBDF \times \frac{1}{2} d - b \times \text{area } OED \times 0.8\, d$$

$$= b\, d^2\, f_c \left(\frac{1}{2} - \frac{0.2}{k^3}\right) \cdots (8)$$

The distance of W from the extreme fibers in compression, $m = \frac{M}{W}$, and the eccentricity under which the column fails,

$$e = \frac{1}{2} d - m = \frac{0.075\, d}{k^3 - \frac{1}{4}} \cdots (9)$$

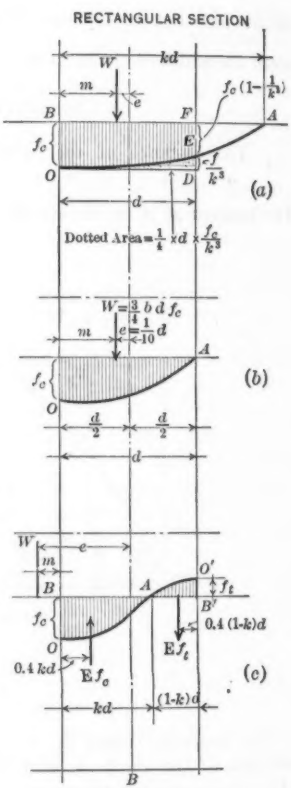

FIG. 13.

For $k = 1$, Equations (7) to (9) simplify to

$$W = \frac{3}{4} b\, d\, f_c, \quad M = 0.3\, b\, d^2\, f_c, \text{ and } e = 0.1\, d. \ldots\ldots (10)$$

For kd smaller than d, or k smaller than 1, we have to distinguish two cases. In one case, as in brick or other masonry columns and in foundations, no tensile stresses can be counted on, and the distribution of stresses will be according to Fig. 14. W equals, again, the area,

Mr. Mensch.

OAB, multiplied by b, and the location of W is given by the centroid of the parabola.

$$W = \frac{3}{4}\, b\, kd\, f_c, \text{ and}$$

$$e = \frac{1}{2}\, d - m = \frac{1}{2}\, d - 0.4\, kd \ldots (11)$$

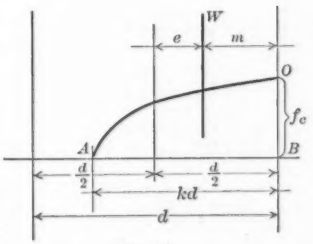

FIG. 14.

It is quite evident that, in this case, W can at no time fall outside of the section. Materials which possess tensile strength will allow W to fall outside, in which case the effect of the eccentric loading will approach girder action. For this case we can only make our theory agree with tests by making a third assumption, namely, that the extreme fibers in tension and compression attain the U. L. P. simultaneously at the time of failure.

From Fig. 13 (c) we have $W + \Sigma f_t = \Sigma f_c$,

or $$W = b \times \text{area } OAB - b \times \text{area } O'AB',$$

$$W = b\frac{3}{4}\, kd\, f_c - b\frac{3}{4}\,(1 - k)\, d\, f_t = \frac{3}{4}\, b\, d\, f_c \left\{ k - (1 - k)\frac{f_t}{f_c} \right\} \ldots (12)$$

$$M = b \times \text{area } OAB \times 0.4\, kd - b \times \text{area } O'AB' \times \{d - (1 - k)\, 0.4\, d\}$$

$$M = \frac{3}{40}\, b\, d^2\, f_c \left\{ 4\, k^2 - \frac{f_t}{f_c}\,(6 - 2\, k - 4\, k^2) \right\} \ldots\ldots (13)$$

$m = \dfrac{M}{W}$, and $e = \dfrac{1}{2}\, d - m$.

Where M becomes negative, m is negative, and it means that the point of application of W falls outside of the section. The ratio of $\dfrac{f_t}{f_c}$ is about 1 for structural steel, $\dfrac{1}{10}$ for concrete, $\dfrac{1}{5}$ for cast iron, and 1.25 for green timber.

Equations (7) to (13) enable us to find W and e for rectangular sections when k is known. By giving k various values from 3 to 0.6, for example, we may obtain a series of values of W and e which will include nearly all cases found in practice. This has been done, and the results may be found in Table 25, Columns 1 and 2. For example, for $k = 1.5$, it is found that $W = 0.926\, b\, d\, f_c$, and $e = 0.024\, d$. The short concentrically-loaded column can carry the load, $b\, d\, f_c$; therefore, the eccentrically-loaded column carries in this case only 92.6% of that load.

The tests by the Committee were made on sections which in most cases can be considered as being composed of rectangles. For the purpose of a simplified theory, we will idealize the sections, like those shown by Figs. 15 and 16. Let A, the entire cross-sectional area, $= 2\, b\, t + d\, s$.

W = Ultimate load ; A = Area of cross-section ; f = Useful Limit Point ; e = Eccentricity.

Mr. Mensch.

Let $\frac{b\,t}{A} = n$, $\frac{d\,s}{A} = n_1$, and $f_t = f_c$. Mr. Mensch.

For bending under right angle to the X-axis and for $k > 1$, we easily find, considering Equations (7) and (8):

$W = b\ t\ f_c + d\ s\ f_c\left(1 - \frac{1}{4\,k^3}\right) + b\ t\ f_c\left(1 - \frac{1}{k^3}\right)$, which easily reduces to

$$W = A\ f_c\left(1 - \frac{n + \frac{n_1}{4}}{k^3}\right) \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

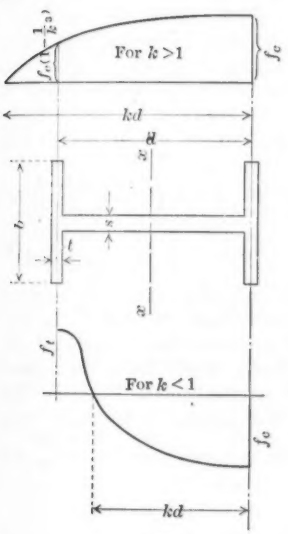

FIG. 15.

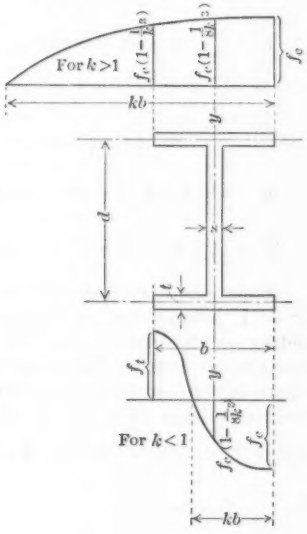

FIG. 16.

$$M = s\ d^2\ f_c\left(\frac{1}{2} - \frac{0.2}{k^3}\right) + b\ t\ f_c\left(1 - \frac{1}{k^3}\right)d,$$

$$M = A\ d\ f_c\left(\frac{1}{2} - \frac{n + 0.2\,n_1}{k^3}\right) \ldots\ldots\ldots\ldots (15)$$

For $k < 1$, $W = b\ t\ f_c + s\ k\ d\ \frac{3}{4}\ f_c - b\ t\ f_t - s\,(1 - k)\,d\ \frac{3}{4}\ f_t$,

for $f_t = f_c$, this reduces to $W = \frac{3}{4}\ s\ d\ f_c\ (2\ k - 1) \ldots\ldots (16)$

$$M = \frac{3}{4}\ s\ kd\ f_c \times \frac{4}{10}\,d - b\ t\ f_t\,d - \frac{3}{4}\ s\,d\ f_t\,(1 - k) \times \tfrac{1}{4}\,d - 0.4\,(1 - k)\,d\,\tfrac{1}{4}$$

for $f_t = f_c$, $M = 0.6\ s\ d^2\ f_c\left(k^2 + \frac{1}{4}\ k - \frac{3}{4} - 10\,\frac{n}{6\,n_1}\right) \ldots\ldots (17)$

Mr. Mensch.

For bending under right angle to the Y-axis, as shown in Fig. 16, and for $k > 1$:

$$W = 2\,b\,t\,f_c\left(1-\frac{1}{4\,k^3}\right)+s\,d\,f_c\left(1-\frac{1}{8\,k^3}\right)$$

$$= A\,f_c\left(1-\frac{4\,n+n_1}{8\,k^3}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

$$M = 2\,t\,b^2\,f_c\left(\frac{1}{2}-\frac{0.2}{k^3}\right)+s\,d\,f_c\left(1-\frac{1}{8\,k^3}\right)\times\frac{1}{2}\,b.$$

$$M = A\,b\,f_c\left(\frac{1}{2}-\frac{6.4\,n+n_1}{16\,k^3}\right) \quad \ldots\ldots\ldots\ldots\ldots (19)$$

For $k < 1$, and considering Equations (12), (13), and (2):

$$W = 2\times\frac{3}{4}\,b\,t\,f_c\,(2\,k-1)+d\,s\,f_c\left(1-\frac{1}{8\,k^3}\right)$$

$$= A\,f_c\left(3\,k\times n-1\times 5\,n+n_1-\frac{n_1}{8\,k^3}\right) \quad \ldots\ldots\ldots (20)$$

$$M = \frac{3}{40}\times t\,b^2\,f_c\,(8\,k^2+2\,k-6)\times 2+d\,s\,f_c\left(1-\frac{1}{8\,k^3}\right)\frac{1}{2}\,b.$$

$$M = A\,b\,f_c\left(1.2\,k^2\times n+0.30\,k\,n-0.9\,n+\frac{1}{2}\,n_1-\frac{n_1}{16\,k^3}\right) \ldots (21)$$

Equations (16) and (17), also (20) and (21), cannot be used for $k = 1$, because the assumption was made that the full U. L. P is acting on the tension side. It is very probable that the neutral axis must be at a fixed proportion of the depth distant from the extreme fibers in tension before these fibers are stressed to the U. L. P. The writer believes that this is the case for values of k smaller than 0.9 or 0.85. When W and M are known, we easily find $m = \frac{M}{W}$ and $e = \frac{1}{2}\,d - m$.

These values have been computed for various values of k and n, and may be found in Table 25, Columns 4 to 17. The values of n were selected in conformity with the specimen tested by the Committee.

For example, Type 1 corresponds to $n = 0.272$
" 1A " " = 0.282
" 2 and 2A " " = 0.33
" 3 " 3A " " = 0.40
" 5 " " = 0.38
" 5A " " = 0.40

To the right of the columns containing the figures for $\frac{e}{d}$ in Table 25 is found another series of figures which are obtained by multiplying

k by $\frac{e}{d}$, giving the values of $\frac{e\,k}{d}$, which are of great importance in the theory of long columns, as will be shown presently. Mr. Mensch.

Theory of Long Columns.—It is known that long columns which are concentrically loaded at knife-edge points fail by buckling. This buckling is the result of some interior eccentricity which, as a rule, is not sufficiently large to produce a noticeable deflection at low loads; but, when the loads become high, especially after the yield point is exceeded in the extreme fibers of a section, the moments are sufficiently large to produce an appreciable deflection. This causes the line of application of the load to fall outside of the center line of the column, as shown in Fig. 17, much more than is due to the original eccentricity, and, under this enlarged eccentricity, the column finally fails. The problem of the strength of a long column is thus reduced to finding the eccentricity of the deflected column. This, of course, is very difficult, because we do not know how large the interior eccentricity is nor how it is distributed, and because we are not yet in possession of the laws governing the flow of the materials after the yield point is exceeded, or of the laws of the deformation of a cross-sectional plane. In the practical column the deflection is so small, in comparison with the length of the column, that we cannot go far out of the way in assuming that the curve of the elastic line is a parabola or a part of a circle. If the radius of the circle is known we can find at once the rise of the curve, and, therefore, the eccentricity of the deflected column.

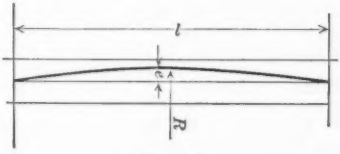

FIG. 17.

Fig. 18 shows a coupon of a column under ultimate load. The original prism, of the length $\Delta\, l$, becomes a bent frustum, and the greatest compressive strain in the extreme fiber equals the U. L. S. (here called ε) multiplied by $\Delta\, l$. We can now find the radius of curvature of the bent column, at the point where the U. L. P. is first reached, by the same reasoning as used in the theory of beams, and can establish the proportion,

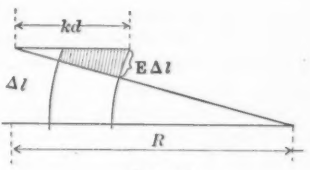

FIG. 18.

$$\frac{R}{\Delta\, l} = \frac{k\,d}{\varepsilon\,\Delta\, l}, \text{ or } R = \frac{k\,d}{\varepsilon} \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

but it is known that, in a circle or a parabola with the radius of curvature, R, at the crown, the rise, $e = \frac{l^2}{8\,R}$, or from Equation (22),

Mr. Mensch.

$e = \frac{\varepsilon}{8} \frac{l^2}{k\,d}$, which can also be written in the form,

$$\frac{e\,k}{d} = \frac{\varepsilon}{8} \frac{l^2}{d^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

The right side of Equation (23) depends only on the known dimensions of the column and on the supposedly known U. L. S., hence $\frac{e\,k}{d}$ can be computed for each column to be investigated. Table 25, however, contains values of $\frac{e\,k}{d}$ for all practical cases; therefore, we can find the strength of a long column in terms of the strength of the correspondingly short column which fails by being stressed to the U. L. P. over the entire section, by computing the value of $\frac{\varepsilon}{8} \frac{l^2}{d^2}$ and by finding in Table 25 the corresponding value for W. The writer has found a good agreement with tests by assuming:

$\varepsilon = 0.0015$ for mild steel, plain concrete, hard brick laid in cement mortar, and for terra cotta block columns;
$\varepsilon = 0.01$ for hooped concrete and for cast iron;
$\varepsilon = 0.004$ for green timber;
$\varepsilon = 0.0026$ for common brick laid in cement mortar.

The conditions of perfectly hinged ends are very rare in a testing machine, as the Watertown Arsenal tests plainly show; such conditions occur, however, in most columns used in building construction, as will be shown later.

The writer will now investigate the behavior of columns with perfect flat ends, such as in the tests which the Committee has presented. As stated before, on account of some slight interior eccentricity, the column will deflect at a certain stage of loading, and, if the ends are not fixed, will try to change their slope, as shown in Fig 19. The platens of the machine being fixed, either by the construction of the machine or by friction, this tendency is overcome by an eccentric application of the load, such as shown in Fig. 20. The form of the elastic line of the bent column with flat ends is similar to that of a uniformly-loaded beam with end restraint. From the ordinary theory of beams, it is known that the moments at the ends are twice as large as in the center. This, however, is only true as long as the yield point is not reached. The fibers of a beam of uniform section will first exceed the yield point at the ends, causing there a

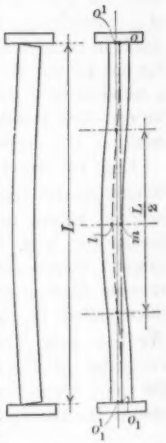

FIG. 19. FIG. 20.

comparatively large deformation, which has the same effect as if the restraint is slightly loosened, thereby allowing the moments in the center to become larger. The few tests which were made on continuous beams, and especially on continuous plates, confirm this reasoning. Probably there is no error, then, in assuming that the new line of application of the load, $o'\ o'_1$, divides the deflection, $l\ m$, in two. It is known, besides, from Euler's theory for very long columns, that this is the case, and that the intersection of the new line of application of the load with the elastic line divides also the column length in two. Mr. Mensch.

Hence, the problem of the strength of a column with perfect flat ends can be reduced to the problem of the strength of a column with perfect hinged ends by assuming the former column to be only of half the length of the latter.

For flat-ended columns, Equation (23) becomes

$$\frac{e\ k}{d} = \frac{\varepsilon}{8}\ \frac{\left(\frac{l}{2}\right)^2}{d^2} = \frac{\varepsilon}{32}\ \frac{l^2}{d^2} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (24)$$

It must be borne in mind that this equation is based on conditions which are not always obtained in the tests. The principal condition is that the moments at the ends shall equal the moment in the center; in fact, the tendency is always there to make the moment at the ends larger. As long as k is greater than 1, every point of the end will be still in contact with the platens of the machine, and the restraint of the ends is bound to be in full action when perfect ends are used; but, where the column is so long that k becomes smaller than 1, only part of the ends will be in contact with the platens, the slope of the ends will change, and we will again approach the condition illustrated in Fig. 19. For the understanding of column action, it must also be remembered that a column with perfectly hinged ends at the time of failure must have a slope at its ends, given by the tangent to the elastic line. It does not make any difference whether we consider the elastic line as a circle or a sine curve, the tangent is given by $\alpha = 3.2\ \frac{e}{l}$, or, substituting the value of e from Equation (23), we obtain

$$\alpha = \frac{3.2}{l} \times \frac{\varepsilon}{8}\ \frac{l^2}{k\ d} = 0.4\ \frac{\varepsilon\ l^2}{k\ d} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Inversely, we can say that a column which has the slope, α, as given by Equation (25), at its ends, must act like a column with ideal hinged ends, regardless of whether it appears to be flat-ended or continuous.

Where the angle at the ends is much smaller than given by Equation (25), the column action lies between that of flat and hinged

Mr. Mensch.

ends. Columns with perfect flat ends are probably extremely rare in actual practice. The rigid heads of the testing machine are infinitely stiffer than the ordinary beam connections in building work. It is known from Euler's theory that ordinary continuation of columns does not make them act as flat-ended. In order to make the column act as a flat-ended one, there must be, at each story, a rigid connection which can transmit the full bending moment, $W\,e$, of the column to the connecting girders without undue deformation—an extremely rare case in practice.

It is a very difficult matter to prove that the quantities, $\frac{e}{d}$, of Table 25, are in accordance with the tests. By inspecting on Plate XXXII the deflections for the middle of the column, we find that, for a load of 280 140 lb. the deflection is 0.3717 in., and for the ultimate load of 289 800 lb. the deflection is 1.995 in., which means that for an increase of 3% of the load, the deflection increases 150%; therefore, the deflections given in Tables 1 to 5 of the report must be considerably smaller than the deflections found by the writer's theory.

To prove that this theory is sustained by the tests of the Committee, Table 26 has been prepared. Only the tests of columns which have sections in conformity with Figs. 15 and 16 were used. The values of $\frac{e\,k}{d}$ were found by Equation (24), and the U. L. P. of each type was found from the average unit ultimate strength for the slenderness ratio of $\frac{l}{r} = 50$ by dividing the ultimate unit stress by the percentage given in the next column.

The percentage of the strength of the short concentrically-loaded column, which a long column carries, was found from the $\frac{e\,k}{d}$ given in Table 26 by interpolation in the proper columns of Table 25. It is found that this theory agrees with the tests in most cases within 5 per cent.

For very short columns, as, for example, the slenderness ratios of $\frac{l}{r} = 20$, this theory does not seem to apply, on account of the so-called block action, for which, at present, the writer has no explanation to offer.

The Committee discourages the use of longer columns than $\frac{l}{r} = 120$, although its tests on $\frac{l}{r} = 155$ still give very high values. That long columns in actual use are so much weaker than short columns is due to the fact that the girders connecting them exert a moment on such columns, cause them to deflect, and change their slopes

at the ends, and we have, instead of the flat-ended column of the testing machine, a hinged column with eccentric loading. Figs. 21 to 34 explain this point. The indeterminate values of the moments and thrusts were found by the slope and deflection method, and the assumption was made that the slope of a girder at the junction with a column is the same as the slope of the column at the junction. The main point to be learned from these figures is the fact that a moment is exerted by the girders on one or both ends of a column, and that the column deflects either like a hinged column of the length, h, or in some cases of the length, $\frac{3}{4}\,h$, and only in very rare cases of the length, $\frac{1}{2}\,h$. Mr. Mensch.

In most cases it will be sufficient to compute a column like a short column, eccentrically loaded by the moment, M, shown in Figs. 21 to 34; but, in the case of very slender columns, it will be necessary to

Mr. Mensch.

find the moment caused by the girder at the point of the greatest deflection of the columns and to combine the eccentricity caused by the moment with the eccentricity caused by the deflection of the column. Mr. Mensch.

As an example, assume a frame like Fig. 27, consisting of two 8-in. H columns, weighing 32 lb. per ft., 30 ft. high, and well connected with a B-30 Bethlehem I-beam, carrying a load of 100 000 lb. on a span of 40 ft.

The moment of inertia of B-30 $= 5\,240$ in.^{4}
" " " " " 8-in. H $= 106$ "

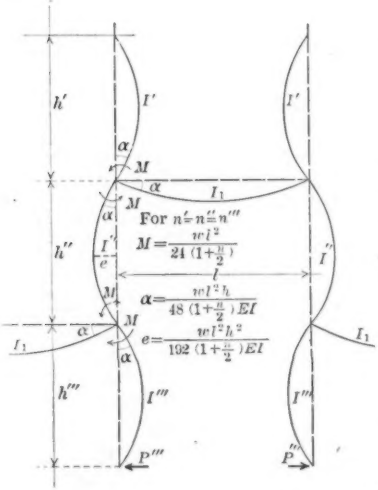
FIG. 32.

Mr. Mensch.

therefore, in Fig. 27, $n = \dfrac{30 \times 5\,240}{40 \times 106} = 37.1$, and the moment at the junction of column and girder, as shown in Fig. 27,

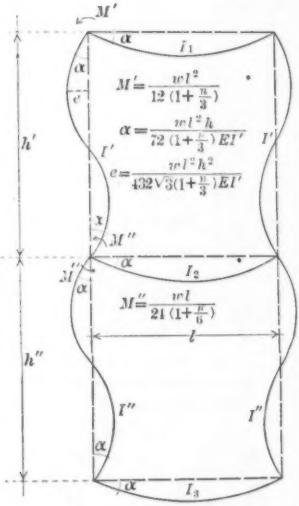
$$M = \frac{100\,000 \times 40}{12\left(1 + \frac{2}{3}\,37.1\right)} = 13\,000 \text{ ft-lb.}$$

If the column is considered as a short compression member affected by this moment, it is found that $e = \dfrac{13\,000}{50\,000} = 0.26$ ft., or $\dfrac{e}{d} = \dfrac{0.26}{0.666} = 0.39$.



TWO THREE-STORY COLUMNS, WITH GIRDERS ON OPPOSITE SIDES OF THE COLUMNS.

FIG. 33.



TWO MANY-STORY COLUMNS, WITH GIRDERS LOADED AT EACH FLOOR.

FIG. 34.

From Columns 14 and 13 of Table 25, it is found that $\dfrac{e}{d} = 0.391$ corresponds to a percentage of strength of 55. Assuming the U. L. P. as 35 000 lb., the column would fail at an average unit load of $35\,000 \times 0.55 = 19\,250$ lb., or a total load of $19\,250 \times 9.17 = 176\,500$ lb. The actual load being only 50 000 lb., or 5 460 lb. per sq. in., the factor of safety is $\dfrac{176\,500}{50\,000} = 3.53$.

If it is desired to consider the deflection of the column, one may proceed in the following manner: The greatest deflection will be at

Mr. Mensch.

the center, and, at the time of failure, is given, according to Equation (23), by

$$\frac{e\,k}{d} = \frac{0.0015 \times 30^2}{8 \times 0.67^2} = 0.75 \ldots\ldots\ldots\ldots (26)$$

The moment exerted by the girder in half of the column height is only one-half the moment at the junction, or 6 300 ft-lb., and the corresponding eccentricity,

$$e_1 = \frac{6\,300}{50\,000} = 0.126 \text{ ft., or } \frac{e_1}{d} = \frac{0.126}{0.666} = 0.189 \ldots . (27)$$

We have now to add $\frac{e}{d}$ and $\frac{e_1}{d}$, in order to find the total eccentricity under which the column fails, but this cannot be done at once, because we do not know, *a priori*, the value of k in Equation (26). The addition must be accomplished by trial. Assuming $k = 1$, we find from Equation (26) $\frac{e}{d} = 0.75$, adding $\frac{e_1}{d}$ from Equation (27), the total $\frac{e}{d} = 0.75 + 0.189 = 0.939$. From Columns 14 and 13 of Table 25, it may be seen that the ratio of $\frac{e}{d} = 0.939$ is between the values of $k = 1$ and $k = 0.85$, and is probably very close to $k = 1$. The values of W and $\frac{e}{d}$ are very unsteady in this region, because the tension flange is affected so greatly by a small change in the position of the neutral axis. Inasmuch as $k =$ nearly 1, $\frac{e}{d} = 0.939$ corresponds to an $\frac{e\,k}{d}$ of nearly 0.939, and, by further trial, it is found that $\frac{W}{A\,f_c} = 0.40$. Hence these columns will fail at a load of 35 000 $\times$ 0.40 = 14 000 lb. per sq. in., and the factor of safety will be $\frac{14\,000}{5\,460}$, or 2.56.

The slenderness ratio of these columns (if they are considered as rigidly held for sidewise deflection) is only $\frac{360}{3.6} = 100$, and yet a stress of only 5 430 lb. per sq. in. produced as low a factor of safety as 2.5 in steel having a U. L. P. of 35 000 lb. A careful analysis of the condition under which a column is loaded, therefore, is of vital importance in its design, especially when the factors of safety are as low as the Committee states. The example chosen is not so rare in practice as it may appear; such cases occur in theater construction and garages, also in railroad crossings in the large cities.

Mr. Mensch.

This theory allows also a clearer conception of the behavior of latticed columns. On account of the final eccentricity of the column as a whole, the stresses in the dangerous section will be unequally distributed, and the magnitude of these stresses can be found from the values of k in the tables. According to whether the column is truly hinge-ended or flat-ended, there exist sections, either at the top or at the quarter points, where the average stresses are equal in magnitude on both sides; and, between these points, the difference of the load on the separate members must be transmitted by the lacing. This transmission of the shears is not uniformly distributed, however; it is greatest near the ends or at the points of inflection.

In regard to the column strength of a latticed column, it must be considered that the eccentricity, e, of the column as a whole, is diminished as the square of the inverse ratio of column length to panel length for each panel, and to this eccentricity must be added the $\frac{e\,k}{d}$ of the separate members between the latticing. There are quite a number of fine points to be considered, and these must be proved by tests, before a definite theory of latticed columns can be established.

Steel Column Committee.

STEEL COLUMN COMMITTEE* (by letter).—The discussions on the Final Report of the Special Committee on Steel Columns and Struts, seem to voice a shade of disappointment because the work of the Committee was not carried to a point where the final word could be said on most of the complex questions relating to the design, ultimate strengths, and safe working values of various types of steel columns.

The report, however, should be looked on as a contribution to general knowledge, rather than as the last word on the subject. It records, as it now stands, what is probably one of the greatest engineering investigations in magnitude, cost, and completeness, even though the larger part of the work first contemplated yet remains undone.

Now that the war is over and two years of reconstruction have been successfully passed, the Committee is of the opinion that the investigation of the theory and practice of column design should be made the subject of study by a special committee of the Society.

For the benefit of future investigators, the Committee desires here to record some additional thoughts, as follows:

1.—Broad Range of Programme.—Table 27 indicates the complete programme as originally discussed by the Committee. The work which has been finished is shown by bold-faced type, and represents what the Committee outlined as the first installment and one which would give certain results within a reasonable time. It is evident that much

* Lewis D. Rights, Chairman, C. W. Hudson, Secretary, James H. Edwards, Charles F. Loweth, Ralph Modjeski, George F. Swain, and J. R. Worcester. Emil Swensson, M. Am. Soc. C. E., a member of the Special Committee, died on May 13th, 1919.

remains to be done before the subject will be covered comprehensively. It is to be hoped, however, that the work so far accomplished has shed some light on the subject, and that the thoroughness of the investigation will eliminate the necessity of repeating this part of the programme. Steel Column Committee.

2.—Variations in Steel.—One of the most important results, in the opinion of the Committee, has been to call attention to the variations in the structural steel in general use. The discussion indicates that many structural engineers are not fully aware even now of this important condition. As substantiating the results of experiments, it is interesting to note the views of metallurgists, two of which are quoted, as follows:

(*a*) In a paper read before the American Iron and Steel Institute, on May 31st, 1918, Theodore W. Robinson, Vice-President of the Illinois Steel Company, says:

"The manufacture of steel is far from being an exact science. It is an art founded upon scientific principles and to a degree subject to scientific control, but there is much in the metallurgy of steel that bespeaks ignorance instead of knowledge, uncertainty instead of definite determination."

Steel Column Committee.

(*b*) In a paper presented before the American Society for Testing Materials (Vol. VI, 1906), Charles L. Huston, a manufacturer of structural steel, stated:

"Under the present standard practice and known methods of manufacture, it is difficult, or nearly impossible, to secure steel that even in one moderate sized plate will have anything like the uniformity generally supposed to exist."

Mr. Huston records very complete tests on a number of ingots, and shows variations in ultimate strengths of the steel, amounting to 19 000 lb. per sq. in. in the same ingot.

It is to be hoped that in the future not only will means be found to control these irregularities, but to allow for them in design.

3.—Conservative Recommendations of the Committee.—It appears to the Committee that the only method of allowing for the irregularities which now occur in strengths of structural steel is to recommend conservative working values. This view has also been shared by the Committee on Iron and Steel Structures of the American Railway Engineering Association in its report for 1920, and by the Joint Committee appointed by the Board of Direction of the Society to confer with a Committee of the American Railway Engineering Association.*

The working formula recommended by the Joint Committee is as follows:

$$P = 15\,000 \text{ lb.} - 50\frac{l}{r},$$

maximum value 12 500 lb., with limiting values of $\frac{l}{r}$.

Although this formula does not agree exactly with the units recommended by the Committee, it indicates that the report of the Committee has had an influence in modifying the formula previously in use.

Paper No. 1457.

NOTES ON THE GUATEMALA EARTHQUAKES, AND EARTHQUAKE-PROOF CONSTRUCTION

By S. Vilar y Boy, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Marsden Manson, A. W. Buel, and S. Vilar y Boy.

Synopsis.

Up to the present time, there has been no possibility of calculating earthquake strains for practical building purposes, due chiefly to the uncertain knowledge of physical conditions of brickwork and masonry in the destroyed or damaged structures. After the use of reinforced concrete had become general in Guatemala, the effect of earthquakes on such structures led to some conclusions as to the destructive power compared with the transverse load for which the damaged or undamaged buildings had been designed, but not much has been done, to the writer's knowledge, in the way of mathematical analysis.

The damage done by the Guatemala earthquake to some steel structures afforded an opportunity to use it as a starting point for more definite study, as shown in this paper.

The abnormal conditions brought about by those earthquakes, together with the World War, compelled the writer to make some tests of various tropical woods which, rough though they are, led him to certain conclusions as to the nature of the strength of wood, which might be extended to other building materials. It also appears from

the results of these tests, that some relation exists between the brittleness of wood and its durability.

The reconstruction of Guatemala City after the earthquakes that practically destroyed it in December, 1917, and January, 1918, together with the difficulties of importing building materials on account of the European War, brought up that question mentioned by Rankine as defining the nature of most engineering problems, "What to do rather than what to think, in order to start on the rebuilding work without delay."

It was necessary therefore to investigate practical and reasonable solutions, disregarding elaborate investigations, and from this point of view the writer endeavored to obtain the necessary data to design several buildings for the International Railways of Central America, with which he is connected, as well as others for private parties who called on him for that purpose.

The first point to be determined was of course the force of the earthquake in order to design the structures to stand for an equal shake with the customary factors of safety. This was quite uncertain since all wrecked buildings had been constructed of materials such as raw brick or adobe, brickwork or common masonry, the physical properties of which vary within wide limits; also because buildings of the same type of construction did, or did not, collapse, depending on their location.

As a starting point, the writer had the records published by the Society on the San Francisco earthquake,* stating that none of the concrete buildings designed for a wind pressure of 30 lb. per sq. ft. had collapsed; also a report on the earthquake in Sicily by the Royal Italian Committee estimating the earthquake impact as equivalent to one-twelfth of the weight of the structure for the ground floor and one-eighth from the second story up. It was necessary, however, to make sure that the Guatemala earthquake had not been stronger than those just mentioned.

The earthquake impact is a force of inertia depending on mass (or weight) and acceleration, the acceleration being, more or less, dependent on the manner in which the structures are supported, as

* *Transactions*, Am. Soc. C. E., Vol. LIX (1907), p. 208.

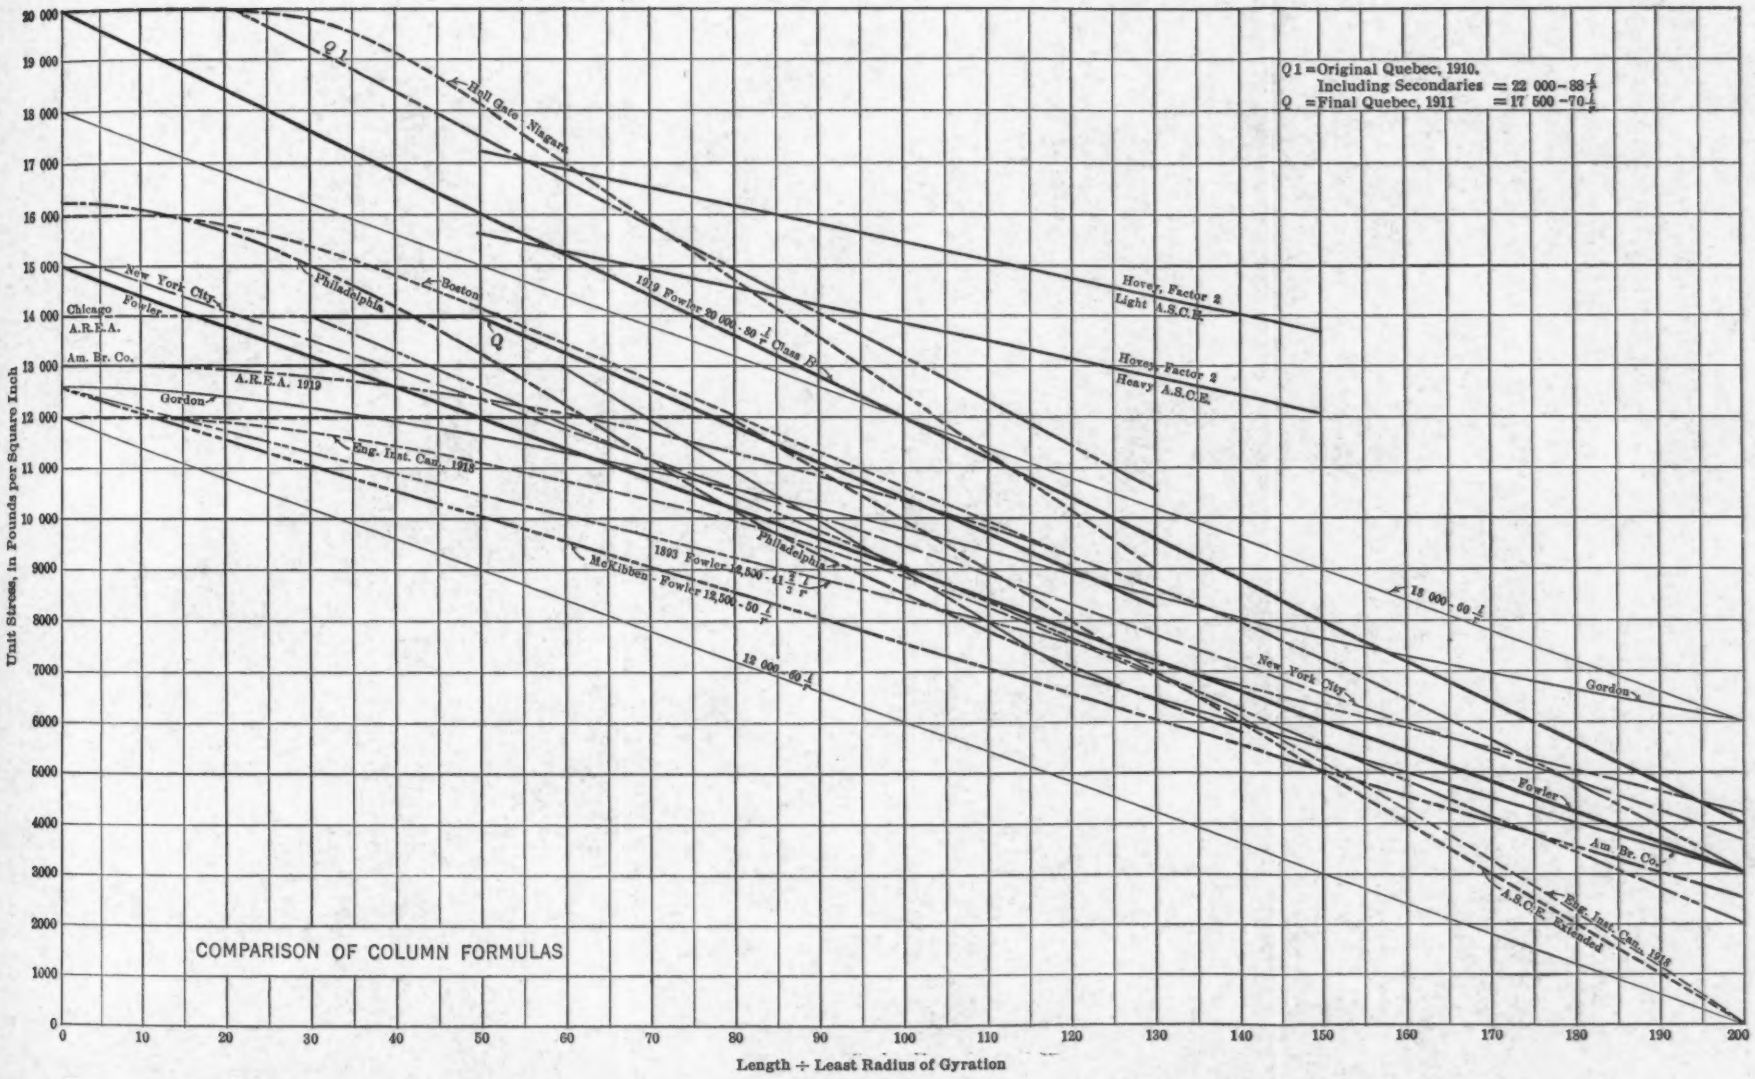
FOWLER ON
REVISION OF
NIAGARA RAILWAY ARCH BRIDGE.



in the theory of impact. That is to say, the earthquake is more destructive on bodies likely to vibrate freely than on structures properly braced.

Bearing these principles in mind, the writer tried to get some instructive data from the ruins of Guatemala City. The only specimens having definite physical properties that could be found were the electric light posts, made of rolled steel I-beams, some of which were bent by the earthquake force. They were strained, therefore, beyond their elastic limit or yield point. Since some did bend and some did not, in the same neighborhood, it follows that they were not strained much beyond the average yield point of steel; otherwise, all should have bent.

Those columns, buried in the ground, were 25 ft. high above the surface and the bend was about 5 ft. above the ground line, as in Fig. 1. The static load, W, equivalent to the earthquake impact, applied at the center of gravity of the bent portion therefore can be obtained as follows, S being the section modulus:

$$W \times 120 = 30\,000\ S.$$

For a 7½-in. I-beam with 3¼-in. flange width and ⅝ in. thick, S was taken as 12. Therefore, $W = 3\,000$ lb.

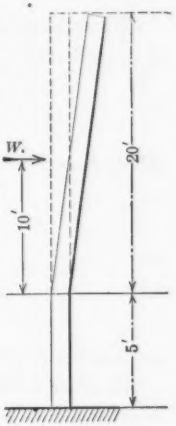


FIG. 1.

This could not be taken as an absolute value for any pole of the same height, but should be considered as a force of inertia for the weight of the bent portion of the beam, or 330 lb. (16.5 lb. per lin. ft. for the 20-ft. length). Hence:

$$\frac{\text{Earthquake Impact}}{\text{Weight of Column}} = \frac{3\,000}{330} = 9.1$$

Or, say, 9, in round numbers, for a pole buried in the ground, free at the top, and acting as a cantilever.

This reasoning was satisfactorily checked by the formula for the acceleration of an earthquake given in the Encyclopedia Britannica, the writer thinks on Milne's authority, as follows:

$$a = \frac{1}{6}\frac{g\,F\,A\,B}{f\,w}$$

in which

a = acceleration per second per second;
F = ultimate strength, or force per unit surface, which when gradually applied produces fracture;
A = area of base fractured;
B = thickness of column;
f = height of center of gravity of column above the fractured base;
w = weight of the portion broken off;

By substituting and calling x the breadth of a rectangular beam, $A = x\,B$, and

$$\frac{A\,B}{6} = \frac{x\,B^2}{6} = S$$

where S is the section modulus for a rectangular beam. Then

$$a = g\,\frac{F\,S}{f\,w}$$

and

$$m\,a = \frac{a\,w}{g} = \frac{F\,S}{f}$$

or, force of inertia $\times f = F \times S$.

In other words: Bending moment due to earthquake impact must equal resisting moment. This coincides exactly with the writer's point of view, and the foregoing computations. These computations apply to a pole with a free end acting as a cantilever under the earthquake transverse force, whereas the walls of a building are tied across by joists or roof trusses which make them act as supported beams. In fact, the pillars and columns with flat ends are about an intermediate case between supported and fixed ends, but if they are dealt with as supported ends the results will be on the safe side.

The likelihood of vibration, for different beams, is measured by the deflection taken under similar loading conditions, and, therefore, the deflection ratio will show the ratio of the force of inertia on a cantilever and a simple beam of the same weight, cross-section, and span.

For the sake of comparison, the writer adopted the formulas for deflections of beams under uniformly distributed loads, although the distribution of forces of inertia along the beam is not uniform. In accordance with this principle, if the earthquake impact on a canti-

lever is 9.1 times its weight, the same earthquake impact on a simple beam should be:

$$9.1 \times \frac{8}{76} = \frac{9.1}{9.5} = 0.95 \text{ times its weight.}$$

Although the assumption of simply supported ends for columns and pillars of buildings, as made in the foregoing computation, results on the safe side against the error due to the non-uniform distribution of forces of inertia along the vibrating beams, the theory was not accepted until checked by facts, the necessary confirmation having been found in the damage done by the earthquake to Las Vacas Viaduct, 3 miles east of Guatemala City. This damage consisted in the shearing of some of the sole-plate rivets connecting the trusses to the towers, although none of the trusses was displaced from the supports.

The Las Vacas Viaduct is 743 ft. long, 203 ft. in maximum height, and its weight is 976 tons of structural steel, with 166 tons of track material, or a total of 1 142 tons. There are seven towers, the damaged ones being 127 ft. high, which is practically the average.

It might be assumed, therefore, that the weight of the part of the structure straining the sole-plate rivets was one-seventh of the total weight, or 163 tons. There are sixteen sole-plate rivets, $\frac{3}{4}$ in. in diameter, on a tower, with sole-plates $\frac{7}{16}$ in. thick. The ultimate strength of these rivets should be 157 tons at the rate of 30 tons per sq. in. The earthquake impact, according to the foregoing theory, should be $0.95 \times 163 = 155$ tons. It is seen that these two figures practically agree.

Again, since only two towers were damaged, it follows that the strain was not much beyond the breaking point; otherwise, all the forces should have given way. Also, in all probability there were along the viaduct some fixed points, or noduli, as there are along vibrating strings.

As to the analysis of the nature of the strains developed by the earthquake, the writer did not even attempt to undertake it, since such strains are of all kinds, oscillation, trepidation, and swirls.

The foregoing refers to the reinforced concrete or steel frame of the buildings, the panel walls of which are brickwork in many cases—the only feasible type of construction in view of the scarcity of cement and steel due to the war. It was quite difficult to determine the earthquake impact on brickwork panels, since the application of the elastic theory

to such a variable material as brickwork is rather uncertain, but for a comparison with other observations they were considered as fixed slabs, since they are held on four sides by concrete pillars and wall-plates. To obtain a simple formula for the deflection of such brick panels, in order to estimate the corresponding earthquake impact, the following theory was applied. From the fundamental equation,

$$\frac{E\,I}{\rho} = M$$

the deflections are proportional to the moments. In ordinary practice it is accepted that the bending moment for a square concrete slab is $M = \frac{W\,l}{20}$, as compared with $M = \frac{W\,l}{10}$ for a beam. That is to say, the bending moment for the slab is half the bending moment for the beam under the same load.

It appears, therefore, to be close enough to assume that the deflection, Δ, for the slab should be half the deflection for a beam with ends fixed, or, say,

$$\Delta = \frac{P\,l^3}{768\,E\,I}.$$

If so, the ratio of the earthquake impact to the weight should be, by comparison with the ratio for a cantilever as obtained in the foregoing, as follows:

$$9.1 \times \frac{8}{768} = 0.09.$$

This agrees quite well with the ratio $\frac{1}{12} = 0.83$, given by the Italian Committee.

A 24-in. wall, assuming its weight to be 150 lb. per cu. ft., should have an earthquake impact per square foot of 25 lb. according to the ratio given by the Italian Committee, or 27 lb. according to the writer's assumptions. Adding a wind pressure of 30 lb. per sq. ft., the distance between the concrete pillars required to prevent the brick panels from collapsing can be computed.

This was done by considering a portion of wall 1 ft. deep, disregarding the slab effect so as to be on the safe side. This section of wall, assumed as a simple beam, would be acted upon by an earthquake impact 0.95 times its weight, and the stress should not exceed the allowable transverse stress, taken as 10 lb. per sq. in. as a conservative value. The

end shear should not go beyond 2 880 lb. and the corresponding weight of wall for half the span should not be more than $\frac{2\,880}{0.95} = 3\,030$ lb. Assuming the weight of 1 lin. ft. of wall, 2 ft. thick, at 300 lb., it follows that a 20-ft. distance between pillars is perfectly safe.

It might be objected that the weight of roof has been neglected in the previously mentioned calculations, but the writer thinks that such weight rather adds to the stability of the walls by bracing them against each other.

As a matter of fact, the inspection of various ruins proved that, in almost all cases, the gable ends of buildings collapsed while the side-walls supporting the roof trusses remained standing in more or less bad shape, which goes to prove that the roof trusses were more of a help than a weakness, in spite of their weight, which, by the way, was rather great, since before the earthquake practically all the roofs in town were of pantiles.

Finally, sufficient reinforcement was allowed in the concrete wall-plates to make a belt around the buildings and main partitions, the tensile strength of which should prevent cracking at the corners, this having been suggested by S. F. Shaw, M. Am. Soc. C. E., at that time Chief Engineer of the International Railways of Central America.

Although the preceding reasoning and calculations are far from accurate, they agree well with facts, and they were developed with the idea of being on the safe side and within reasonable limits.

Tests of Native Woods.

In connection with the reconstruction work, some tests were made of several kinds of wood which are not commonly used for building purposes, with a view to adopting those passing the tests satisfactorily. The writer thinks the results of his investigation might be of use to engineers in tropical countries, if not as absolute values, at least as a guide.

The investigations were based on some fundamental ideas pointed out in the discussion of a paper by Henry S. Prichard, M. Am. Soc. C. E., on "Faults in the Theory of Flexure",* that is, the transverse deformation of materials depends not only on the strength of fibers themselves, but on the bond between fibers as well, especially in wood,

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 895.

the fibers of which adhere to each other by means of such a variety of cementing substances. Furthermore, some connection between the elasticity of timbers and their durability was sought as a check to supplement the chemical treatment, as explained later.

Among cementing substances, the albuminoids and carbo-hydrates are food for fungi and insects. It was the writer's opinion that all kinds of wood with a high modulus of elasticity, E, as compared with ultimate transverse strength or modulus of rupture, R, which ratio might be called "modulus of brittleness," would contain a large quantity of albuminoids and sugar, and hence attract fungi and insects and cause rapid weakening and decay; also, that there should be some more or less constant ratio between the durability in the ground and the resistance to artificial decay by chemicals. The only chemical available at that time for applying the latter test was the hypo-sulphite of soda commonly used in photography, which was substituted for the sulphite of lime to make paper paste.

By comparing the behavior of some known and some relatively unknown kinds of wood through these tests, the writer expected to arrive at some reasonable conclusions in regard to durability. The rough means of experimenting available at the time make the figures, given later, unsuitable for accurate calculations, but approximate enough as a guide.

The transverse bending strength, R, and the coefficient of elasticity, E, were determined by simply supporting a beam 1 in. square on supports 24 in. apart, the center breaking load consisting of old castings and track bolts, the deflections being measured by a thread stretched between supports. For this case, the ordinary theory of flexure leads to the following expressions:

R = ultimate strength in bending = $36 \times$ center breaking load

$$E = 3\,456 \times \frac{\text{Center load}}{\text{Deflection, in inches}}.$$

Four specimens of each kind of wood were tested, the deflections being measured under five different loads for the same specimen. The timbers were unseasoned; in fact, they were samples sent by the proposed contractors.

The chemical treatment was applied by putting a slice, $\frac{1}{4}$ in. thick, of the broken 1-in. beams in a vessel made of a 3-in. nipple closed with

pipe plugs at the ends, the vessel being filled with 75 cu. cm. of a solution of hypo-sulphite of soda with a strength of 36% and 3 cu. cm. of hydro-chloric acid with a density of 1.08. These vessels were enclosed in a cylinder connected to the shop boiler and fitted with a steam gauge to maintain the unit pressure at 45 lb. during 45 hours.

After treatment, the specimens were tested with a home-made Vicat needle, 1 mm. square, weighing 5½ lb., the penetration of which afforded a comparison between the known and relatively unknown woods.

Each specimen was tested ten times. Most of the native woods that were tested have never been classified, and it is impossible, therefore, to give their scientific names, but engineers who have worked in the tropics will very likely recognize many of them. By comparing the results obtained for the known woods, it was considered that values of the modulus of brittleness under 150 are favorable, as a rule, but for very strong woods, the ultimate transverse strength of which is more than 13 000 lb. per sq. in., values of the modulus of brittleness might be acceptable up to 200.

A needle penetration of less than 2 mm. appeared to be favorable. The strength of chemicals and time of steaming were determined by trial.

The results of the tests are given in Table 1.

TABLE 1.—Results of Tests of Tropical Woods.

Sample No.	Name of wood.	Modulus of rupture, R, in pounds per square inch.	Modulus of elasticity, E, in pounds per square inch.	Modulus of brittleness, $\frac{E}{R}$	Size of nail splitting specimen.	Needle penetration after treatment, in millimeters.

19..	Güayacan.....	.....	.....	...	....	Practically nil.

Sample No. 1, Sangria.—There were contradictory reports about this sample, Sangria, because of different woods with similar names.

Sample No. 2, Sangre.—This is very similar to Sample No. 1, but of a lighter weight and of the undesirable kind; the results of the tests made it possible clearly to differentiate both kinds.

Sample No. 3, Leche Amarilla.—On account of its yellow juice, the third sample had the name "Leche Amarilla". The ultimate transverse strength 10 605 lb. per sq. in. is the average of four specimens, one of which was as low as 7 000 lb.

Sample No. 4, Santa Maria.—Some foundation blocks of Santa Maria were reported to be perfectly sound after five years in the ground.

Sample No. 5, False Mora, or Fustic.—A specimen of an odd wood was received, the sender claiming that it was Mora or Fustic which during the war was exported as dyewood. The results of the tests are as given in Table 1. The needle penetration of more than 2 mm. and the modulus of brittleness under 150, but very close to it, contradicted the well-known lasting qualities of Fustic. This being the case, the original log was examined by a wood expert and compared with a log of true Fustic, with the result that it was found that the sample was not true Fustic.

Sample No. 6, True Mora, or Fustic.—The results of tests of true Mora or Fustic were as stated in Table 1. The needle penetration was inappreciable and the specimen could not be broken with the fingers as had been done with more or less difficulty with previous samples. This harmonizes with the writer's assumptions and the well-known durability of Fustic, but leads to allowing values up to 200 for $\frac{E}{R}$, if R is more than 13 000.

Sample No. 7, Hormigo.—The sapwood of Hormigo rots out very quickly, although its heartwood has proved satisfactory in actual practice. The specimen used had a fair percentage of sapwood. The modulus of brittleness was rather high, due to the sapwood in the sample, whereas the slice used for chemical treatment was practically all heartwood.

Sample No. 8, Red Chichique; Sample No. 9, White Chichique.—There are two varieties of Chichique, red and white, which lead to contradictory reports. The red variety has a life of, say, 5 years in the ground. The unfavorable results for white Chichique are confirmed by

actual practice, as the white variety is rotten after being 2 years in the ground.

Sample No. 10, Chichipate.—This wood has a very good reputation in actual practice. This specimen was rather well seasoned, as it came from car-shop stock.

Sample No. 11, Nance.—This was reported as giving satisfaction in the ground for foundation blocks.

Sample No. 12, Native Pitch Pine.—The penetration was quite variable, sometimes being as much as 3.5 mm. There are reports of some posts of this quality rotting after 2 years in the ground.

Sample No. 13, Campanillo.—This wood has proved to be fairly good in actual practice.

Sample No. 14, Güachipilin.—This wood is very good in actual practice.

Sample No. 15, Genizaro.—This is fairly good in actual practice.

Sample No. 16, Laurel (Atlantic Side).—There is a very good wood called black laurel on the Pacific Coast, and some samples were brought from the Atlantic Coast with the expectation that they would be as good as the others. The tests showed, however, when compared with Sample No. 17, that this expectation was not fulfilled.

Sample No. 17, Black Laurel.—The results for this wood confirmed its lasting qualities and are quite different from the laurel on the Atlantic side, Sample No. 16.

Sample No. 18, Madrecacao.—The results for this wood require no comment.

Sample No. 19, Güayacan (Lignum Vitæ).—No sample of the required dimensions for the physical tests was available, but for the sake of confirming the effectiveness of the chemical treatment, a small sample on hand was subjected to it. The needle penetration was nil.

Several specimens of unknown woods were tested, as well, and by comparison with the results for the samples as listed in Table 1, some reasonable probabilities were obtained as to their lasting qualities, which made it possible to accept or reject them in contracts.

The foregoing tests were made more than a year ago, but sufficient time has not yet elapsed for actual experience to confirm or contradict the results, although they agree fairly well with the information available at the time.

DISCUSSION

Mr. Manson.

MARSDEN MANSON,* M. AM. SOC. C. E. (by letter).—This contribution on the Guatemala earthquake and earthquake-proof construction is a valuable addition to the professional studies and literature on this subject.

At best, the efforts to determine the strains produced by earthquakes are as much empirical as analytical. In the San Francisco earthquake of April, 1906, three chimneys in the same building were twisted and displaced laterally at the roof plane in different directions and to variable distances, showing that each yielded to forces applied in different directions and at different times, and that a certain joint or joints which yielded to the first displacing and rupturing strain was near other joints which were unaffected and which yielded to subsequent strains in a different direction. The same was true in failures of other types.

The writer was Chairman of the Sub-Committee on Statistics, of the Reconstruction Committee, and in that capacity investigated several thousand buildings in San Francisco, some within and some beyond the burned area. From the report then rendered the following extracts are taken:

"In presenting data, the Sub-Committee feels justified in adding general remarks and suggestions based on its observations. The suggestions and recommendations are submitted with the hope that they will be fully considered by owners, and that they may result in the most scrupulous regard of all provisions of the architect and engineer when stability and safety are concerned, whether as regards fire or earthquake. With the lessons before us, it is the unanimous opinion of your Sub-Committee that the greater portion of the loss sustained could have been prevented by a clear interpretation and regard for the lessons of 1868 and the fires which have devastated this and other cities.

"Even in the destruction of water mains it is apparent that with mains constructed on solid ground or adequate foundations over critical ground and with ample service reservoirs and fire cisterns, and with well-equipped fire-tug service having shore connections to mains, our disastrous losses of hundreds of millions of dollars would have been measured by tens of millions and probably by a less sum.

"*Small Frame Buildings, Wooden Underpinning.*—In general, these buildings suffered severely owing to the rotten condition or original weakness of the underpinning. The mudsills and adjacent parts of posts and braces had, in many instances, rotted, and the buildings settled vertically, as in a row of frame buildings on the west side of Webster Street, between Eddy and Turk Streets; or they settled laterally, as in the case of one-story frame buildings on the southeast corner of Bush and Steiner Streets, and on the south side of O'Farrell near Devisadero Street. In most instances of this kind very flimsy construction was originally permitted. The damage to the upper parts of these buildings was at times so severe as to totally wreck the buildings.

* San Francisco, Cal.

Mr. Manson.

"*Small Frame Buildings, Masonry Foundations.*—These stood well, the damages being generally restricted to loss of chimneys and consequent injuries to roofs, walls, and gutters.

"*Large Frame Buildings, Wooden Underpinning.*—In general, a stronger original construction and broader base enabled these structures to stand well. Damages to roofs and sides by falling of chimney tops from the building itself or from adjacent buildings constituted the major portion of the damage. In some instances, the roofs were not able to withstand massive chimneys with high fall.

"When masonry foundations were provided, these buildings suffered less, and numerous instances were observed where no damage whatever was done, notably the three-story frame building on the northeast corner of Washington and Gough Streets, where the chimneys, by reason of first-class construction, remained intact, and the building itself shows no evidence of strain. It may be here observed that buildings of this type, well constructed, diagonally boarded and braced, metal or wire lathed, and with chimneys of reinforced concrete or brick, well laid in cement mortar, are perfectly safe in a severer shock than that of April 18th, 1906.

"*Class 'C', Brick Walls, Wooden Partitions, Floors, and Posts.*—This class of structure has quite a variety of applications, being used for dwellings, stores, storehouses, churches, libraries, etc. When properly constructed, they stood the shock well, particularly if the walls were tied and bonded and the mortar good. Some, however, had two fatal defects—weak or badly laid mortar and unbraced gable ends. Churches, large storehouses, carhouses, barns, etc., were injured, the gable ends being especially weak. This defect has been brought out prominently in this, as well as in higher classes of buildings. Notable instances are on the northeast corner of California and Webster Streets, the south end of the Ferry Building (Class 'A'). Numerous other instances were observed, especially where lime mortar had been used, not at all or but slightly strengthened by the addition of Portland cement; and where fairly good mortar had been badly used or the bricks laid dry, instead of soaking wet, as they should be in good work.

"A marked instance of failure from poor mortar is on the south side of Geary Street, near Fillmore, where well bonded brickwork fell to pieces, and stone veneer, without bond, scaled off the lower story. This scaling is frequently the case in the pressed Roman brick used as facing, without bond, or fastened against wooden buildings with weak metal ties. Failures from these causes have been so general that they have caused universal comment, and it is hoped that the lessons will result in the thorough testing of all cements and other materials and their proper use, as a matter of safety not only to the owner, but to the public in general.

"Equally notable cases of the standing of well-built structures are frequently noticed. The U. S. Appraisers' Building on Sansome, Washington, and Jackson Streets, although partly on made ground, did not suffer the slightest injury, due to the excellent quality of mortar and good workmanship. A seven-story building on the south side of Eddy Street, 100 ft. east of Jones, although subsequently burned, its walls of well-bonded brick, with good mortar, stand intact. Other instances are

Mr. Manson.

the Jewish Tabernacle on the north side of Sutter Street, between Stockton and Powell Streets, the church on the northwest corner of Fillmore and Jackson Streets, and the one on the southeast corner of Fillmore and Fell Streets.

"Class 'B', Brick or Masonry Walls, Steel or Cast-Iron Posts, and Steel Girders Protected Against Fire, Metal-Lathed Partitions, etc.—The damage to this class of buildings by earthquake was, in general, light; no instances of well-constructed buildings of this type were observed which suffered more than a small percentage of damage. A notable instance is the reinforced and well-built walls of the Palace Hotel, which withstood both fire and earthquake.

"Class 'A', Steel Frame, Non-Combustible Floors and Partitions.—The thoroughness with which these structures withstood the earthquake has been so frequently recorded that it is not necessary for the Committee to note further facts. The most severe injury was to the slim and heavy tower of the Ferry Building, and the south unsupported gable end. This structure stands entirely on piles, 80 to 90 ft. long, driven into harbor mud some 15 to 20 ft. below city base. Yet it withstood the shock, with the exceptions above mentioned, and a few minor injuries to marble wainscoting. Another instance of damage to this class is the north wall of the building at Sacramento and Mason Streets. Buildings of this class, in process of construction, were injured where mortar had not yet set, but hardly a joint was sprung in those which were caught with the frames partly constructed.

"With corrections as to fire coverings of posts and beams and the use of metal frames for doors and windows, with wire glass and proper window protection, it has been demonstrated that this class of buildings will withstand both fire and earthquake, and, with a local supply of water, can be made absolutely safe, even in a general conflagration. But no building in which combustible material is stored will escape a general conflagration, unless an adequate water supply and men to use it are available. Inferior buildings, under these conditions, were saved, and superb Class 'A' buildings, without water, were totally destroyed. This lesson cannot be too thoroughly impressed upon owners and officials.

"Effects of Earthquake on High Stacks and Chimneys.—These structures were generally severely damaged or broken. They are of several cross-sections, circular, square, polygonal, and intersecting squares. Those having square sections appeared to stand best. The percentage of stacks escaping injury is so small that your Committee recommends that in the future these be entirely of metal or of heavily reinforced concrete or reinforced brickwork; in these two latter cases that only cement mortar of the highest strength be used.

"Chimneys.—Chimneys suffered proportionately more severely than anything else. This was due to three causes: (1) worthless mortar; (2) bad workmanship; and (3) unusual strains at the joints of roofs with the chimneys where weakened further by flashings. To overcome these defects will be simple but will require good materials and first-class workmanship. Chimneys stood where well constructed, proving that well selected materials and good workmanship are proof against severer shocks than that lately experienced. To accomplish this result, your Committee recommends: First, that either lime mortar of stand-

ard proportions reinforced with one-third Portland cement, or Portland cement mortar be used with reinforcing steel rods at roof joint and above; or, second, that reinforced concrete of the best quality be used. Mr. Manson.

"Flue linings have resulted in placing reliance upon these, and using flimsy brickwork on the outside. Brick chimneys properly built are safe and strong under any conditions yet experienced, and the linings serve as a subterfuge to lessen the cost and efficiency of one of the best materials of which chimneys can be built, namely, good brickwork.

"*Mortar.*—The results warrant the absolute rejection in the future of lime mortar unless well seasoned and reinforced with Portland cement, and the most stringent supervision should be had over the testing and use of this latter. Inferior cement and poor workmanship will make weak structures ready to fail when the test of actual strain or use comes. Every yard of concrete and every brick laid in the future should be mixed and laid with scrupulous care. Concrete can be made as worthless as much of the brickwork was in this city. Hence it must be made of the best materials, properly mixed, laid and rammed to secure good results; and bricks must be sound and well made, carefully laid when soaking wet in the best lime-cement or cement mortar. These classes of work will insure safety in earthquake shocks of greater severity than that experienced in April, 1906, and with the added security of an ample water supply, proper protection of posts and girders, and guarded openings to all masonry buildings, will make such general and widespread disasters as that following the morning of April 18th, 1906, absolutely impossible.

"*Retaining Walls.*—Retaining walls have long been a source of expense and danger in San Francisco, the percentage of these failing from various causes has always been large. In a city of such variations of level they are necessarily much used. Both ordinary and surcharged walls failed from lack of sufficient gravity section and inadequate footings. An instance of both these deficiencies is in the overturned surcharged wall on the west side of Gough Street, between Pacific Street and Broadway. Instances of each were noted. As examples of well-constructed retaining walls, the Committee notes those on Pine, Powell, and Mason Streets, and on the south side of California Street, west of Presidio Avenue, which, with others, withstood the shock without injury, proving that properly constructed retaining walls can be relied upon with confidence.

"*Monuments and Statuary.*—These slender structures withstood the shock well. In cemeteries, some were overthrown. The Dewey Monument in Union Square was reported 'standing at an angle of 10 degrees'. An inspection shows that the sections were barely displaced and the pedestal very slightly spalled at a few joints, and that, to the ordinary eye, the monument stands unscathed by either earthquake or fire. Monuments and groups of statuary in other portions of the city were uninjured.

"*Conclusion.*—The Sub-Committee on Statistics finds:

"(1).—That well-built structures of all classes generally withstood the earthquake without serious injury, and that the majority of these structures were unharmed.

Mr. Manson.

"(2).—That the principal damage by earthquake was due to inferior workmanship, worthless mortar, or faulty design. As instance the City Hall, in which the design of the building is radically unsuited both to the requirements and to the strains likely to occur. Immense gable ends and cornices resting upon massive columns, not well tied to the remainder of the building, were the cause of damage to a far greater extent than inferior mortar and workmanship, as has been alleged. The fragments of masonry lie in large masses rather than in individual bricks, as in many other fallen walls. The same is true of the church on Bush and Pierce Streets, and other instances. These are deficiencies which can be remedied in the future.

"(3).—That losses by fire were in the greater part due: (*a*) to the utter failure of the pipe system, as made manifest by the extinguishment of fires where a meager water supply was available; (*b*) to lack of protection to openings in masonry buildings, and, in the burned buildings of Classes 'B' and 'A', to the additional lack of adequate fire coverings for posts and girders, causing collapse of these members in Class 'B' and in some instances in Class 'A' buildings. These are also defects which can be remedied so as to lessen insurance risks and rates and ultimate damage in case the contents of these structures should burn.

"(4).—That Class 'C' buildings constitute the poorest and most dangerous structures, and should be restricted in use, steel framed and galvanized iron sides and roofs being preferable. Also, that a greater use should be made of non-combustible materials, steel, concrete, galvanized iron, metal lathing, etc., than the present fire and building laws admit. This will be to the advantage of owners and the greater safety of the city.

"(5).—The members of this Sub-Committee feel that too great importance cannot be laid upon the thorough inspection and testing of cement and other building materials and upon the most conscientious workmanship, and are assured that craftsmen of all branches cannot render a greater service to the community nor to themselves than by refusing to do work of any kind which is not up to a high standard of workmanship; for neither themselves, their families, nor any one else will be safe, nor property secure, with such flimsy work as has characterized many buildings of all classes of structures in this city.

"Streets and lots graded with waste and loose materials of all kinds are not suitable foundations on which to make sewers and pavements nor erect homes or buildings for human occupation and use, nor are sewers and buildings with inferior mortar and poorly laid brick on filled areas of this kind more likely to stand in the future than in the past.

"The causes of our great losses may therefore be briefly stated: (1), Failure of water supply due to insufficient number of service reservoirs and cisterns, and to fractures of the mains and connections where constructed over made ground and marshes and over or immediately adjacent to faults—mains should be altogether on solid ground, or on the heaviest of masonry and pile foundations, and service reservoirs and cisterns should be more numerous and larger; (2), Flimsy construction, and in some instances, improper design; (3), Absence of

adequate door and window protection for masonry buildings; (4), Lack of efficient covering for posts and girders in Classes 'B' and 'A'. Mr. Manson.

"The necessity for constructing buildings of incombustible materials has been made fully apparent. These buildings must meet all requirements, from the costly and elaborate steel cage, concrete walled, and floored structure with metal doors, window frames, casings and finishings, to the cheap steel-framed shed, covered and roofed with galvanized iron. To meet these requirements, the following sub-classes of Class 'A' are suggested:

"*Class 'A'-1.*—Steel-cage construction, concrete, brick or tile walls and floors; metal-framed doors, windows and finishings; plate wire glass windows, asbestos curtains inside.

"*Class 'A'-2.*—Concrete or brick walls; steel posts concrete or tile-covered; concrete steel or tile floors; steel-framed, metal-covered roof, fire shutters.

"*Class 'A'-3.*—Reinforced concrete walls; steel-framed roof, metal covered.

"*Class 'A'-4.*—Light steel frame; walls, metal lathing or expanded metal, plastered with cement mortar on one or both sides of framework; concrete, steel or tile floors; metal roof; metal-framed windows and doors; plate wire glass; asbestos curtains, for light stores or dwellings, etc.

"*Class 'A'-5.*—Steel frame, corrugated iron sides and roof for sheds and lightest buildings; if more than one story, upper floors of steel and concrete or tiles.

"*Class 'A'-6.*—Any combination of the above classes which is structurally sound.

"It will be observed that each of these classes is composed of incombustible materials, that they vary in cost from the costly skyscraper to a cheap steel-framed, galvanized-iron shed, and will thus meet the wide requirements of cost, and at the same time afford a reasonable but imperative safety. The mortar to be either lime cement mortar or cement mortar.

"If the radical deficiencies above outlined be remedied, San Francisco will have but little to dread from even a more serious earthquake than that of April 18th, 1906; and if, in rebuilding, we make stability and thoroughness the prime essentials of all work, these characteristics will mark our recovery and development in every line to the remotest future."

The writer is of the opinion, after personal inspection, that most of the loss of property and life in recent earthquakes in Italy and much of that throughout Mexico, was due to the use of weak lime mortar and that thinner walls of good masonry or, better, of reinforced concrete with greater resilience and the use of well-framed timber buildings on well-laid masonry foundations would have greatly lessened the losses; and that these requirements should be prescribed in regions subject to earthquake.

The unanimous opinion of the Sub-Committee sustained the views expressed in the quoted portions of the report. The Sub-Committee

Mr. Manson. was composed of the following, all of whom are members of the Society: Edwin Duryea, the late Virgil G. Bogue, C. H. McKinstry, John W. Reid, and the writer, who acted as Chairman.

Mr. Buel. A. W. BUEL,* M. AM. SOC. C. E. (by letter).—The analytical investigations of the author promise valuable data on the destructive force of earthquakes, if he can supply more detail to support his assumptions and conclusions. His method appears to be rational, but the writer, who spent the past winter in Guatemala and had his attention called to one of the bent or twisted trolley poles and many other failures, does not find the author's assumptions entirely convincing. It is important to know the exact angle made by the plane of the bend with the web of the I-beam, and if exact sketches, with dimensions, of as many of these bent poles as can be secured, are added to his paper, the author will greatly enhance its value and make of it a really useful contribution.

While in Guatemala the writer noted that many of these I-beam trolley poles had been seriously corroded at the point where they enter the pavement (or ground), in some cases showing a loss of about one-half the original section on probably two-thirds to three-quarters of the resisting moment. It is important to know whether the bent poles had suffered loss of section and at what points. The condition of the fixed ends should also be recorded, that is, whether they were in concrete or other pavement, or in earth. Were the span wires in place when the poles were bent?

The author's example of the Las Vacas Viaduct leaves the assumptions far from clear, although this structure was designed by the writer. A sketch of the "sole-plate" referred to, showing its relation to the structure, should be added. Were the sole-plates sheared under both trusses on the bent or only under one, and was it a fixed or expansion end? Full details are necessary in order to check this analysis.

As to the weight involved, it is not even approximately true that a tower of "average" height represents average weight per linear foot, especially as the maximum height is 230 ft. and the minimum about 50 ft. from base of rail to masonry in the Las Vacas Viaduct. Moreover, if the writer understands the author to refer to a shearing force at the point where the spans rest on the top of the bent, only a fraction of the weight on the pedestals of that bent should be considered, or the weight above the point of shear. Then, on the header of a bent there is the weight of one-half of one intermediate span and one-half of one tower span. This viaduct has been described in four articles in *Engineering News-Record*,† which will perhaps be of some assistance in studying this question. After some consideration and reference to these articles, the writer is much in doubt as to whether the action

* New York City.

† Vol. 54, p. 638; Vol. 55, pp. 104 and 118; and Vol. 56, p. 297.

was simple shear or how the forces acted; only full details of the failure can establish this point. Mr. Buel.

After all, the question remains how do earthquakes differ in type and velocity of vibration? S. F. Shaw, M. Am. Soc. C. E., who was in Guatemala during the entire month, describes the four principal "quakes" as differing in type, but states that all of them were due to explosive volcanic action as distinguished from earth slips. He also thinks that he located, approximately, the center of the disturbance at a point a few miles southwest of the city. Now Las Vacas Viaduct is farther away—several miles—in the opposite direction. What effect, if any, has distance from the disturbance on acceleration and velocity?

S. Vilar y Boy,* Assoc. M. Am. Soc. C. E. (by letter).—The writer agrees with Mr. Manson that a great deal of trouble in the case of earthquake disasters is due to poor materials and workmanship, together with faulty design. Mr. Vilar y Boy.

The conclusions reached by the Committee on the San Francisco Earthquake are the result of a most complete compilation of data, far beyond anything that the writer was able to make, without giving up his everyday work. The Committee's report gives facts as to whether the different structures did or did not stand, with general remarks about them, without going into the question of how much these structures were strained above or below the yield point, whereas this is the point which the writer tried to investigate, within reasonable limits of accuracy, with reference to the Guatemala earthquakes. It appears, therefore, that the writer's point of view does not contradict the Committee's conclusions and should only be considered as a complement to its general remarks.

The writer did not think of preparing a paper on this subject for the Society at the time of the Guatemala earthquake, and, therefore, failed to take photographs or to obtain any other evidence of the failure of the trolley poles, outside of the notes required for his own guidance.

According to Fig. 1, however, the specimens taken into consideration for analysis were bent practically in the plane of the web at a point 5 ft. above the ground, and their full cross-section was ascertained by measuring with calipers in any given case. Also, these poles stood by themselves at the street corners and there were no signs of any pieces of wall having fallen on them, thereby causing them to bend under the ramming effect of collapsing walls rather than their own inertia.

They were five or six poles which happened to be included in a lot bought by a contractor, Mr. W. T. Penney, for use as floor-beams in rebuilding a private residence under the writer's supervision. That

* Guatemala, Guatemala.

Mr. Vilar y Boy.

work was finished in 1918, so that the specimens which Mr. Buel mentions are not the ones referred to in the paper, but some others which the writer disregarded altogether, due to their defective condition, or evidence of walls having struck them. Two or three of the poles taken into consideration were slightly twisted, which shows that the initial bending did not take place on the plane of the web, as assumed, but somewhat sidewise. If so, and since the plane of the web corresponds to the maximum moment of inertia, the assumption is on the right side.

The deflection at the top of the poles averaged 12 in. Their ends were in earth well packed with boulders, but no concrete, and they also had, for insulation, a wooden casing of 1-in. boards all around up to the point where they bent, the wooden casing entering the ground as well and being fastened with iron hoops.

The total top deflection does not seem to be of much value in estimating the force of the earthquakes, because after the initial bend took place, straining the poles beyond the yield point, their resisting ability decreased at every subsequent shake, of which there were perhaps fifty during the night of December 25th, 1917.

Some of the span wires were in place, running parallel to the streets, whereas the plane of the beam webs was at right angles to the wires, which therefore did not act as guy lines. There were three wires, and their size varied from, say, No. 2 to No. 6 gauge, which is rather light weight.

Relative to the Las Vacas Viaduct, it was taken into consideration simply as a means of checking the fundamental assumptions, and, as plainly stated in the paper, the writer did not even attempt to analyze the complex succession of oscillations, trepidations, and swirls.

As to the weight involved in measuring the equivalent static effect of the earthquake, it is beyond dispute that the assumption of average weight for average height is far from true, but it should be borne in mind that the earthquake impact depends on two factors, as stated in the paper, namely, the weight and the likelihood of vibration. This was a most difficult question for such a complex structure as the viaduct, and an effort was made to simplify it by "reasoning with figures" without attempting to present it as an analysis.

For this purpose, the whole of a tower was considered as a vertical pole, somewhat supported at the top, and its likelihood to vibrate was worked out on the same line as that which Professor Merriman in his "Mechanics of Materials" refers to as a cantilever with constraint, with the only difference that Professor Merriman deals with a concentrated load at the top, whereas in the case of the earthquake it is a distributed load, the weight of the tower itself.

Under these circumstances, the integrations of the elastic curve are as follows: Mr. Vilar y Boy.

$$E\,I\,\frac{d^2\,y}{d\,x^2} = M_1 - \frac{w\,x^2}{2} \qquad E\,I\,\frac{d\,y}{d\,x} = M_1\,x - \frac{w\,x^3}{6} \qquad M_1\,l = \frac{w\,l^3}{6}$$

$$M_1 = \frac{w\,l^2}{6}$$

$$E\,I\,\frac{d\,y}{d\,x} = \frac{w\,l^2\,x}{6} - \frac{w\,x^3}{6} \qquad y = \frac{1}{E\,I}\left(\frac{w\,l^2\,x^2}{12} - \frac{w\,x^2}{24}\right)$$

$$y_{max.} = \frac{w\,l^4}{24\,E\,I} = \frac{W\,l^3}{24\,E\,I}$$

Therefore, the likelihood of the viaduct towers to vibrate as cantilevers with constraint, as compared with a plain cantilever, bears the ratio of $\frac{8}{24}$ or $\frac{1}{3}$ and if the earthquake impact for a cantilever is 9.1 times its weight, the same impact for the viaduct towers should be 3.03, or about three times its weight.

The weight to be considered, however, is only a fraction of the weight of the tower which, on account of the anchorage, was considered as fixed at the bottom and simply supported at the top.

In order to consider the extreme conditions, the corresponding distribution of weight (equivalent to the transverse strain) was calculated for the highest tower, the posts of which are built as follows, starting at the bottom:

One section, 35 ft. high.....	2	I-beams,	80	lb.	per ft.
One section, 29.5 ft. high.....	2	"	75	"	" "
One section, 29.5 ft. high.....	2	"	65	"	" "
Three sections, 29.5 ft. high....	2	"	55	"	" "
One section, 32.3 ft. high.....	2	"	55	"	" "

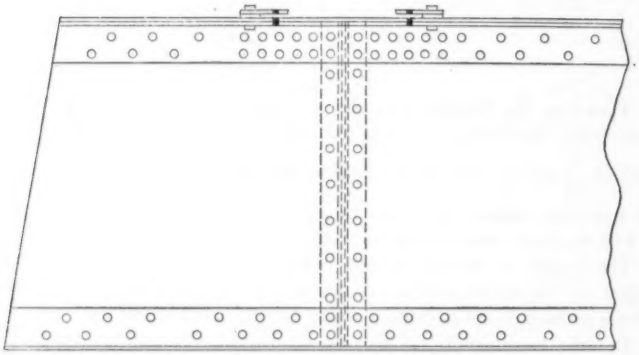
The center of gravity of these sections should be 116.8 ft. from the top, and the corresponding fraction of weight as a measure of earthquake impact transmitted to the top should be 0.27 of the total weight, according to the well-known formula: $2 - 3\,k + k^3$. The likelihood of vibration as previously described, however, multiplies the factor 0.27 by 3, making the fraction of tower impact at the upper end equal 0.81 times the weight of the complete tower in the extreme case. This coefficient does not greatly differ from 0.95, as found for a supported beam, and justifies for practical purposes the writer's rough assumption that the earthquake impact for the whole weight of the viaduct, disregarding the different effect of towers and trusses, especially bearing in mind that vibrations should be transmitted pretty well through an elastic material like steel, and that any increase in the reaction of the tower

Mr. Vilar y Boy.

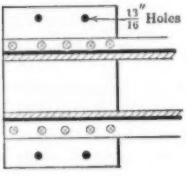
top, due to the bottom not behaving as a perfectly fixed end, would bring the factor, 0.81, up to almost 0.95.

Fig. 2, traced from detail drawings, will clear up the question of how the forces acted to cripple the rivets. The reasoning applies to a fixed end; but, in fact, there were sole-plate rivets cut both at one fixed and one expansion end, which otherwise do not greatly differ in

DETAILS OF LAS VACAS VIADUCT.



Cross-beam, showing anchorage of trusses.



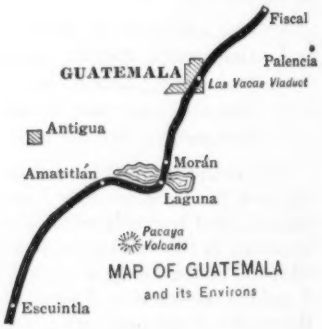


FIG. 2.

design, the only difference consisting in substituting slots for round holes. The fact that the results of these calculations agree with the actual ultimate strength of rivets confirms the computations.

Regarding velocity of vibrations and influence of distance, the writer regrets the lack of the necessary seismographic stations, so that

Mr. Vilar y Boy.

no definite information can be supplied. As far as he could rely on his senses at the time of the disaster, the seismic waves came from about the south, which agrees with the location of the Pacaya Volcano (Fig. 2), Lake Amatitlan, and the Town of Moran, destroyed by an earthquake in November, 1917, about a month prior to the ruin of Guatemala City. In all probability, however, the center of disturbance was between Lake Amatitlan and Guatemala City, and the subsequent earth displacement followed a fault line, as evidenced by a deep crack toward a volcanic hill near Palencia. Otherwise, Escuintla and Antigua would have suffered as much as Guatemala City, which is not the case.

This might compensate for the increased distance from the supposed center of disturbance to Las Vacas Viaduct, 3 miles from Guatemala, along the railroad, and explain the damage suffered by the viaduct. Lake Amatitlan showed evidence of volcanic activities at its south shore, where there was a strong steam-blow through a crack running toward the Pacaya Volcano; but, in all probability, it was simply a case of a geyser originating at the bottom of the lake, 25 ft. deep at that point, and the surface crack was only the outlet of a zigzag conduit coming up from below. The steam jet was intermittent, increasing and decreasing by 8-min. cycles, as though the pressure of steam generated by water percolating into some deposit of anhydrous rocks stopped any further action until that pressure was released through the surface outlet.

The temperature was 134° Cent. for steam jet, with no signs of hydrochloric or sulphurous acids, 62° Cent. for the soil, 50° Cent. for the water on the lake surface, and 28° Cent. for the atmosphere, from which the average heat transmitted per square meter per hour should be about 218 calories and, therefore, the thickness of material between the atmosphere and the steam should be about 1.37 m., which seems to prove that the outlet conduit did not come straight from the bottom, but through a crooked zigzag line, and, therefore, its direction at the surface should be disregarded. The computed thickness was confirmed when that place caved in later.

The report of the Committee on the San Francisco Earthquake should be considered first to determine the general stability conditions of any earthquake-proof construction. After these general conditions are established, the writer's method of calculation will assist in designing properly the required structure, proper design being one of the conditions emphasized by the Committee.

The likelihood of vibration as a factor of the earthquake impact agrees fairly well with failures observed in Guatemala, and in the case of the Las Vacas Viaduct the discrepancy between the two factors, 0.81 and 0.95, can be explained by the bottom of the towers not behaving

Mr. Vilar y Boy.

altogether as perfectly fixed ends. This is not a mathematical reason, but such is the case with the assumption that a pillar with flat ends represents the intermediate condition between supported and fixed ends, which assumption does not prevent its being accepted in ordinary practice.

Moreover, with reference to earthquakes it would be useless to look for analytical refinements, since the forces of Nature cannot be standardized, and the results obtained from a complete analysis of one earthquake would not agree mathematically with the next one. For the sake of protection of life and property, however, it appears that the customary permissible stresses applied to the strains resulting from the study of the Guatemala earthquakes in 1917-18, which completely destroyed a town of one-story buildings, should afford a reliable guide as far as human foresight can control natural phenomena.

Paper No. 1458.

HYDRAULIC-FILL DAMS*

By Allen Hazen, M. Am. Soc. C. E.

With Discussion by Messrs. C. E. Curtis, Richard D. Chase, G. A. M. Elliott, J. M. Howells, D. C. Henny, A. T. Goldbeck, George L. Dillman, H. B. Muckleston, H. F. Dunham, William H. Burr, M. M. O'Shaughnessy, Arthur E. Morgan, H. deB. Parsons, George Sidney Binckley, Charles H. Paul, John E. Field, J. Albert Holmes, H. W. Swanitz, Joel D. Justin, and Allen Hazen.

Synopsis.

The hydraulic method of dam construction has great advantages, but too many dams built by it have failed.

As often built, the center of the dam is composed of a clay core completely water-tight, but very wet as a result of the method of construction, and so completely water-tight that it is incapable of permitting its own drainage.

This soft core in the center of the dam exerts the pressure of a liquid of high gravity on the toes and tends to push them out. This pressure seems to have been responsible for most of the failures of hydraulic-fill dams.

The method of placing the core commonly used results in an exceedingly fine-grained material, desirable from the standpoint of a water-tight dam; but it may be that extreme tightness is secured at the expense of stability.

To use the hydraulic method of dam construction successfully, it is necessary either to increase the toes until they are large and heavy

* Presented at the meeting of May 5th, 1920.

enough successfully to resist the full fluid pressure of the core, or else to handle the core material so that the finest particles are wasted, leaving only the larger ones, and in that way increasing the grain size to a point where drainage can be secured, while on the other hand remaining sufficiently impervious for practical purposes.

Methods of testing are described and an effort is made to analyze the conditions of stability.

The hydraulic-fill method of dam construction grew out of hydraulic mining. It was natural that a process conspicuously successful in mining on an enormous scale, and which moved material at very low unit costs, should find other applications.

The late James D. Schuyler and J. M. Howells, Members, Am. Soc. C. E., were pioneers in the application of hydraulic methods to dam construction. Mr. Schuyler presented a paper* to the Society in 1906 setting forth in a most admirable way the peculiarities of the method and its application to actual dams.

The method is certain to have an important place in future dam construction. It has two fundamental advantages: First, in sorting out the fine particles and placing them in the center of the dam, thus insuring complete water-tightness; and, second, in the use of power in place of muscle to the greatest extent, so that the labor cost and the animal cost of construction are reduced to a minimum.

It is sometimes possible to place material by the hydraulic process at much smaller cost than by any other method.

On the other hand, several hydraulic dams have not proved to be stable. Failures, usually during construction, have caused great losses, and their occurrence has been discouraging.

There may have been more than one cause of failure, but one cause has certainly predominated. In the interior of the dams there have been masses of clay and other fine-grained material, that have not consolidated to the point of stability. Instead of forming an integral part of a solid dam, these masses have remained in almost liquid form, dividing the dams and tending to disrupt them. In this respect, hydraulic-fill dams are on a different basis from other earth dams.

If the hydraulic method of dam construction is to be used successfully, this element of weakness must be eliminated.

---

* *Transactions*, Am. Soc. C. E., Vol. LVIII (1907), p. 196.

There seem to be two promising ways of eliminating it. The first and most natural one is to increase the size of the dam until the solid parts forming the toes are amply strong to resist the full fluid pressure of the unstable core. The second consists in selecting material and handling it in a way to secure drainage and consolidation of the core, so that the whole dam will act as one solid mass.

If core material can be fully drained and consolidated, there is no reason why a dam built by the hydraulic method on a section that is suitable for an earth dam built dry should not be safe. If drainage and consolidation of the core are not secured, however, safety can only be reached by making each toe large enough to stand the full pressure of the liquid core, and in that case, in order to be safe, a dam built by the hydraulic method must have flatter slopes and a larger section than is otherwise needed for an earth dam.

It is interesting to note that Clemens Herschel, Past-President, Am. Soc. C. E., in discussing Mr. Schuyler's paper in 1906, made the point that a larger section would be required for stability; Mr. Schuyler took exception to this, and stated that in his experience there was no reason for building a dam of greater dimensions because the material was placed in it by the hydraulic method.

The advantages and economies of the hydraulic method are such that it will often be good business to use it, even though the required volume of the dam should be greater. If work can be built at half the cost per cubic yard, twice as many cubic yards can be placed for the same money.

The number of failures with hydraulic-fill dams growing out of this fundamental condition of fluid cores and inadequate toes has been such as to make it clear that this condition of instability has not been recognized in the designs. Mr. Schuyler's excellent paper contains no discussion of this point. Looking at it from the standpoint of thirteen years afterward, it is easy to see how this condition could have been overlooked and to see, also, how some of the early failures were attributed to other causes.

Now, however, enough experience has been gained so that a better analysis may be made. To insure success with future hydraulic dams, this analysis must be thorough. It is the writer's thought that it will be possible to make it in a way to secure as high a degree of safety in hydraulic-fill dams as is required, and is customary, in other engineer-

ing structures. It may be that we do not yet have all the necessary data; but, if not, the best way to find what is lacking is by using what we have.

Character of Core Material.

The first point to be considered is that, in many or perhaps most hydraulic-fill dams, the core material is so fine in grain size that it is incapable of drainage. By that is meant that it is incapable of drainage within a reasonable length of time. The lower parts of the core do not become stable before the upper parts are placed upon them.

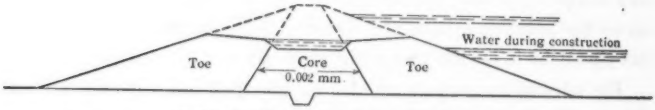
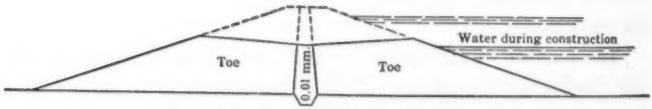
FIG. 1



TYPICAL SECTION OF HYDRAULIC FILL
DAM DURING CONSTRUCTION.
FIG. 2



ILLUSTRATING PROPOSED SECTION WITH
NARROW COARSE-GRAINED CORE.
FIG. 3

In general, all the material placed in hydraulic-fill dams may be divided into two classes, namely, toe material and core material. Mr. Schuyler presented a diagram of materials divided into several classes, the coarsest being found at the outside and the finest in the middle (Fig. 1*). Practical experience does not show that the material is graded in quite that way. There is some grading in the toes and the average size of particles near points of delivery of material near the outer slopes is

* Fig. 1 is reproduced from *Transactions*, Am. Soc. C. E., Vol. LVIII (1907), p. 243.

greater than away from those points and near the core; but, practically speaking, this gradation is not very important. Ordinarily, all the toe material is of coarse particles when first placed. Afterward, passage of silt-laden water from the operation of hydraulicking partly fills the voids with fine material, but the process stops itself before they are all filled. The toes drain readily and all the stability naturally inherent in the stock is obtained.

The core may be defined as that part of the dam deposited from water in the central pool. In the writer's experience, core material is homogeneous. At any level there is no appreciable difference in grain size between the middle of the core and its farthest extremities.

The principles determining the size of particles deposited in the core, or not deposited, are the same as those that apply in a sedimentation basin of a water-works plant. The larger the area of the pool in proportion to the quantity of water that goes through it, the more complete will be the subsidence, and the smaller will be the limit of size of particles retained.*

Most hydraulic-fill dams have been built with good-sized pools in the center during construction (Fig. 2), in which sedimentation has been fairly complete. The writer has examined samples of the core materials from a number of dams. The samples are rather surprisingly alike in grain size. They ordinarily contain particles in large quantities down to a limit between 0.001 and 0.002 mm. (or sometimes 0.003 mm.) in diameter. Generally speaking, all smaller particles have been carried away by the escaping water and have not remained in the core.

It should be stated that the determination of the exact size of these small particles is by no means as precise as the determination of the size of grains of filter sand. The results are reached by the microscope with a micrometer and are to be considered as roughly approximate only. It has been the intention to use a basis as nearly as possible comparable to that adopted for the larger particles in sand analysis, which is to use as the diameter of any particle the diameter of a sphere of equal volume. Following this rule the width, rather than the length, of small particles is measured.

Core material then, as a matter of observation, consists of particles from this size up to the size of the smallest particles retained in the

* "On Sedimentation," by Allen Hazen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 45.

toes. In a general way, this size may be taken as 0.03 mm., or ten to fifteen times as great as the limit of size of particles that are retained in the core.

Speaking of core materials in the terms that are used in describing sand; it may be stated that the effective size of core material is ordinarily about 0.002 mm. This size is so small that one who is not accustomed to microscopic work has little conception of it. For comparison, it may be stated that ordinary filter sand has an effective size of from 0.3 to 0.4 mm., while dune sand, being the finest material usually spoken of as sand, has effective sizes ranging from 0.15 to 0.20 mm.

Without attempting precision, and using round figures, the core material is one-hundredth of the size of dune sand. This means (assuming that the laws of flow and the laws of capillarity applying to the finest sands apply also to these still finer materials) that, other things being equal, the drainage of core material will take ten thousand times as long as corresponding drainage of fine sand. Fine dune sand would drain as much in an hour as core material in a year. It means, further, that the height to which water can be held by capillarity is ten thousand times as great as the height at which it is held by fine sand. If fine sand will hold water by capillarity to a height of an inch, as it will, then core material like that shown by the samples will hold water by capillarity to much more than the full height of any dam.

The reason why this core material does not drain is therefore clear. It seals itself up and becomes practically water-tight.

With the dimensions existing in dams that have been built, assuming that the laws of flow known to apply to the finest sands apply also to the still finer materials, it will take years for the excess of moisture to drain out, as it must do before the solidification of the material is possible.

As a practical proposition, drainage is not possible with such fine materials. By that is meant such prompt and complete drainage as will result in solidification during the construction of the dam.

Construction records and samples show approximately what happens. Core material of the fineness already described goes down first in the form of soft mud in which the voids filled with water are at least 70% of the total volume. Such mud is very soft.

The percentage of voids furnishes, on the whole, the best index of consolidation and stability. In itself, it is not an adequate basis of

comparison, because different kinds of core material may have different degrees of stiffness with the same percentage of voids; but, notwithstanding this difference, the percentage of voids is the best index of consolidation so far available.

The material when it goes down contains 70% of voids. Under these conditions, the minute solid particles are held apart by the water contained between them, and the passages through which water can pass are much larger than they would be with a more compact arrangement of the same material. Water drains from this material gradually, and the material consolidates.

The drainage may be horizontal, in which case the surplus water finds its way through the core material to the toes and escapes. There is, however, a shorter way out, and it appears probable that most of the drainage takes place vertically. That is to say, the solid particles settle down and consolidate while the water moves upward between them to the top. This consolidation takes place gradually at rates depending on the dimensions of the dam and also on variations in the effective size of the core material; for while the writer considers all this material broadly as having an effective size of 0.002 mm., there are no doubt considerable variations in size and permeability.

Experience shows that consolidation goes on so that after a period of from a few months to two or three years in the ordinary course of dam construction, the material will have been consolidated to a point where the voids are about 50 per cent. As the consolidation increases, the sizes of the passages between the grains become smaller, the flow becomes less rapid, and the process of consolidation goes forward more and more slowly.

Material with 50% of voids when taken out of a boring is described as material having the consistency of stiff putty. It is capable of standing up in a boring driven beyond the casing for several feet, and it offers great resistance to penetration.

One of the best field methods of testing the consolidation of core material has been to find the depth to which a 1¼-in. pipe could be forced into it by two men. This method of testing has been used in several dams. It has been possible to co-ordinate the penetration so found with records of the percentage of voids. In a general way, penetration by 1¼-in. pipe pushed down by two strong men extends to the point where the voids are about 50 per cent. In other words, the 50%

material is so stiff that it can no longer be penetrated to any considerable depth by this method.

Tests of material by letting down cannon balls, etc., are less searching. The penetration does not go as far.

Material with 50% of voids in a considerable depth acts essentially as a liquid. It exerts the full lateral pressure corresponding to its height and weight per cubic foot, and when the resistance of the toe is overcome, this material moves forward and flows. Precise limits cannot be set, but this is the general result of observation at Calaveras as a result of determinations of voids in many samples of material that did flow and in other samples of material that did not flow. This refers to the Calaveras Dam* near San Francisco, Cal., which slipped as it was approaching completion on March 24th, 1918, investigation of which afterward gave an unusual opportunity for studying some of the conditions that grew out of the methods of placing material that had been used. (See Figs. 4 to 6.)

Core material becomes solid when it is dried. Core material dried in the summer sun at Calaveras was consolidated until only 35% of voids remained. In this condition, it was only a little less strong and stable than the natural sandstone in the neighboring hills.

Core material consolidated to 35% of voids would form the strongest and most stable kind of an earth dam. No large toes would be required to contain it, for on any reasonable slope it would be stable by itself. Such consolidation, however, as far as is known, is reached only by complete drying. Unfortunately, drying cannot be applied to the core of a large dam.

Without attempting precision of statement, it is the writer's judgment that if core material like that at Calaveras could be consolidated to 40% of voids, it would be sufficiently stable to do its share toward resisting the pressures that come on the dam without tending to disruption. Perhaps this degree of stability would be reached before consolidation had proceeded as far as 40% of voids. There is a middle ground of uncertainty. Material with 50% of voids is still unstable; and between this limit and 40%, one cannot be certain just where to draw the line.

* See *Engineering News-Record*, April 4th, 1918, p. 679, and December 26th, 1918, p. 1158.

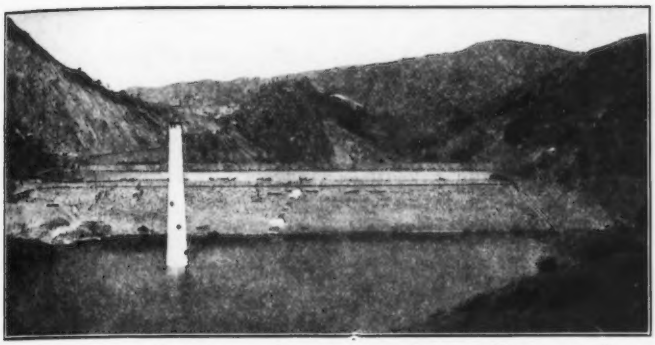


FIG. 4.—CALAVERAS DAM DURING CONSTRUCTION, SHOWING UPPER AND LOWER TOES, WITH POOL BETWEEN. WATER IN FOREGROUND IS IN RESERVOIR ABOVE DAM.

FIG. 5.—CALAVERAS DAM DURING CONSTRUCTION, SHOWING TOES AND CENTRAL POOL A FEW DAYS BEFORE THE SLIP.

FIG. 6.—CALAVERAS DAM AFTER THE SLIP. ON MARCH 24TH, 1918, 800 000 CU. YD. OF MATERIAL MOVED 300 FT. UP STREAM AND DROPPED 100 FT. IN ELEVATION, TURNING ALSO 30° TO THE RIGHT.

It is interesting to note that the 1½-in. pipe used in the penetration tests only reaches to points where the material is still unstable. It follows that tests of this kind do not and cannot demonstrate stable material. Tests made by cannon balls or other less searching means are equally defective. It cannot be considered, in the light of the Calaveras experience, that tests made by such methods throw much light on conditions of stability. They may at times serve a purpose in showing lack of stability, but that is as far as use can be made of them.

It is the writer's thought that the best method of investigating consolidation and stability is by making borings. There are difficulties, for boring usually involves stopping the sluicing of material while the holes are being put down; but it does lead to more definite results. Borings can be driven and samples taken from the bottom of the borings for physical inspection and for determination of the percentage of voids.

The Determination of the Percentage of Voids.

This is a very simple matter, but experience shows that it is easy to go wrong, and for that reason a brief statement of methods that have been found suitable will be given.

The samples taken from the bottom of test borings are saturated with water. A determination of water content, therefore, can be made a measure of voids. This procedure is sound so far and only so far as the voids are completely filled with water. A useful check can be obtained from the specific gravity of the moist material.

The specific gravity of the solid particles of core material may be taken as 2.65. It may be that in some locations other specific gravities will be found, but, in the writer's experience, actual values differ little from this mean value.

In determining the specific gravity of these exceedingly small particles, the most careful manipulation is required to get all the air out of the dry material. Methods similar to those used for determining the specific gravity of Portland cement are appropriate, but water can be used.

A table can be made showing the weight of the solid particles, the weight of water, the percentage of water by weight, and the specific gravity of core material containing various percentages of voids.

Table 1, in convenient and somewhat condensed form, gives these values for saturated clay.

TABLE 1.—SATURATED CLAY.*

Specific Gravity of Solid Particles, 2.65.

Percentage of voids.	Percentage of water, by weight.	Specific gravity. Wet.	WEIGHT PER CUBIC FOOT.

70	46.8	1.495	93.4	49.6

* This table is not to be used for any material that has lost water by evaporation so that the voids are not completely filled with water.

When a sample is taken from a test boring, a portion is put in a dish and weighed. The weighed material is dried at or above the boiling point to constant weight, and the percentage of moisture computed. As even a little drying before the first weight affects the result, the samples should be weighed on the spot when first brought to the surface; to do this, portable equipment must be used. After the first weighing, samples may be taken to the office or laboratory for the completion of the process. When the percentage of moisture

by weight is found, the corresponding percentage of voids is obtained from Table 1.

As a check, the specific gravity of another part of the sample is determined. This is obtained by putting a weighed portion of the moist mass into a graduated cylinder partly filled with water and noting the increase in water level. The specific gravity is the ratio between the weight of material added and the weight of the water that corresponds to the increase in level, and so to the volume of material placed in the cylinder. With this specific gravity determined, Table 1 indicates the percentage of voids.

The percentage of voids determined by the two methods with good manipulation should check within 1 or 2 per cent. If it does not, there is something wrong and the error must be found and eliminated.

To determine the weight of the coarse and hard toe material, no better method has been found than to make an excavation accurately to a dimension of 1 cu. yd., or other convenient size, and to weigh the excavated material on platform scales. Percentages of moisture vary, and the weight of dry material affords the best basis of comparison. An average sample of material on the scales is taken for determining the percentage of moisture, and the results are reduced to weight of dry material per cubic foot.

Draining Fine Material.

The writer is fully satisfied that there is no practical way of rapidly draining core material as fine in grain size as that described previously. He has considered it from a theoretical standpoint and also from the standpoint of practical experience.

After the material reaches a condition of 50% of voids, 6 cu. yd. must be compressed into 5 cu. yd. of 40% material by the exclusion of 1 cu. yd. of water before full stability can be counted on. This water, amounting to one-sixth of the whole volume of core material, must be expelled. The computed rate of flow through material with an effective size of 0.002 mm. is very slow. The rate depends on, and is proportional to, the hydraulic slope. With a slope of 10% (which is as steep as is usually found) the computed rate of flow as a solid column of the full area of the section is 0.32 mm. daily. At this rate, 80 days are required for the water to move 1 in. and 2.6 years for it to move 1 ft. This calculation cannot be used with assurance as estab-

lishing the exact rate of flow, but it is the writer's judgment that the actual rate is as likely to be below as above the result given. It is clear that, for a large dam, complete drainage and consolidation may be a matter of many years.

From a practical standpoint, it may be recorded that a 6-in. well driven 60 ft. in saturated core material having voids averaging 50%, with the casing perforated freely to admit water, stood empty for weeks. Not enough water drained from this material to raise the water in the well. This may represent the effect of capillarity. With such a degree of tightness, it is clearly useless to attempt to secure consolidation by any method depending on additional drainage outlets.

Measuring Core Pressures.

An interesting method of measuring the pressures actually existing in core materials has been suggested by A. T. Goldbeck, Assoc. M. Am. Soc. C. E.* By this method, small test cells are built into the core material. Some are placed with horizontal and some with vertical faces, arranged to indicate pressures on the faces during construction and afterward. Such devices are reported to have been placed in hydraulic-fill dams now building by the Miami Conservancy District. The results of observation through a certain period have already been recorded. These observations indicate, as would be expected, that the horizontal and vertical pressures are the same at first and until the material has become somewhat consolidated. Afterward, horizontal pressure increases less rapidly than vertical pressure, and the inference may be drawn that this represents solidification of the material in which the cells are placed to a point where the full horizontal pressure is no longer produced.

This is certainly an interesting method of test and one that may throw light on the conditions of core material.

It reminds the writer of one of his early experiences, which related to different circumstances, but possibly the same underlying principles are involved. It was proposed to build large and heavy structures in which the weight would be well distributed on a foundation of stiff silt. The question was presented as to whether the foundation was sufficient to carry the weight. An apparatus was provided by which test areas of 1 sq. ft. at the level of the proposed foundation were

* *Engineering News-Record*, April 18th, 1918, p. 758.

loaded. The results of the tests were most satisfactory. The material carried more than the expected loads, with only insignificant settlements. When the actual structure was built, however, there was considerable settlement. The actual settlement was many times greater than had been indicated by the tests.

The explanation is simple enough. The single square foot that was loaded distributed the weight applied to it to a much larger area a short distance below. What was loaded was in effect a pyramid with a flat top of 1 sq. ft. The full applied weight per square foot was carried only at the top, and the unit stress rapidly became less going downward as the area of the pyramid increased. A thin layer of material just below the footing actually got the pressure and was compressed accordingly, and in this way the slight observed settlement was produced. Lower down, however, the unit pressure was lower and there was no appreciable compression.

When the structure was built there was no chance for a corresponding distribution of pressure. The whole area underneath was loaded, and the weight had to be carried through the full depth of silt and the silt was compressed. A corresponding settlement would no doubt have taken place in the test apparatus if the material loaded had been a column 1 ft. square all the way down to rock. The writer thinks that because of this dispersion of load it is generally true that a small test area will carry more per unit than a larger one, and it may be that the same conditions will be found to apply to the test cells built into the core of a dam.

In view of all the information now available, the only safe course to follow, so long as the core material is like that here described, is to assume that it will produce the full horizontal pressure corresponding to its weight and height; and the toes must be made large enough to resist that pressure with ample safety.

Resisting the Pressure of the Core Material.

The first point to be considered is the coefficient of friction of the material in the toe, sliding either upon the foundation or upon itself. With hard, clean gravel a coefficient of 0.7 or 0.8 might reasonably be expected, although the data for establishing this coefficient are not as convincing as could be desired. No such coefficient was found, however, in accounting for the Calaveras slip. Instead, it was esti-

mated that the weight of the material pushed forward in the up-stream toe was five times as great as the pressure of core material against it. In estimating that pressure the whole height and weight of core material was included, assuming that it acted as a heavy liquid. This indicated a coefficient of friction of only 0.20. This is to be taken as an average for the whole area on which the slip occurred. It may be recorded, however, that a similar calculation for the lower toe which did not slip indicated a coefficient of 0.22. No one can tell how much more it would have held.

The Calaveras material is softer and perhaps more slippery than the hard particles of glacial drift of the Eastern States; and it would not be reasonable to expect as high a coefficient of friction. It may be, also, that the coefficient of friction under such heavy pressures as are found in the lower part of a high dam will be less than under the small pressures of moderate depths.

Some experiments were authorized by George Wilhelm, M. Am. Soc. C. E., and made by G. W. Hawley, M. Am. Soc. C. E., Resident Engineer at the San Pablo Dam, near Berkeley, Cal. (see Fig. 7), following suggestions of the writer. A 14-in., cast-iron pipe was cut into two short parts, one of which was fixed and the other attached securely to a steel frame which swung freely on an axis about 8 ft. above. Another steel frame securely connected the ends of this axis with the fixed part of the 14-in. pipe and with other parts of the apparatus. Two hydraulic jacks were used and the pressures were computed from the measured pressures on the pistons.

The two pieces of 14-in. pipe were placed in line and the frames held them so that the ends would just clear.

A sample of the material to be tested was placed in the pipe, filling the lower or fixed part and extending some distance into the movable part. Oak planks, cut to fit as a loose piston, were then placed above. One of the hydraulic jacks was placed above it. Pressure was then applied to compress the material in the pipe to any desired extent. Experiments were made with various pressures, the greatest corresponding to a depth of fill of 200 ft. While the material was held under this pressure, the other jack was placed horizontally against the side of the 14-in. pipe with suitable blocking, and pressure applied until there was movement. The ratio of pressures on the two jacks then gave the coefficient of friction.

FIG. 7.—SAN PABLO DAM, SHOWING DEVELOPMENT OF LOWER TOE, WITH THE FINER MATERIAL PASSING OVER IT TO THE CENTRAL POOL.

The steel frame and the pivot at the top were built so that there was no appreciable friction in the apparatus. A slight correction was necessary because the lever arm to the slipping plane was longer than the lever arm to the point on the 14-in. pipe where pressure was applied.

The form of the experimental apparatus was suggested to the writer by a paper by Mr. A. L. Bell on clay pressures.* The apparatus as worked out was more like that used by E. P. Goodrich, M. Am. Soc. C. E., in his experiments on soil pressures.†

The apparatus used differed from both of its predecessors in that tests were made at very much higher pressures. The results may be compared, but it must be remembered that the local material had peculiarities of its own, and that it was no doubt quite different physically from the material tested by Messrs. Bell and Goodrich.

The writer will not attempt to discuss this matter further, but suggests it as a fruitful topic for further experiment.

Experiments were made by Mr. Hawley with various local materials at various pressures. These showed that, with low pressures, the coefficient of friction was distinctly larger than it was with higher pressures. The explanation for this may be that the higher pressures broke down and crushed the particles, and so reduced the relative resistance. After a certain pressure was reached there was less rapid change in the coefficients, and for the higher pressures the coefficients for any material were practically constant.

For material from the local soft sandstone rocks at San Pablo, coefficients of friction of approximately 0.5 were found.

There was one kind of material more slippery than the others for which an average coefficient of 0.45 was found. Other harder materials gave coefficients of 0.55 and more. Sand and gravel from the creek representing the remnants of much harder rocks in the hills (and so corresponding more nearly to the glacial drift of the Eastern States) gave coefficients of about 0.7.

The materials at San Pablo are similar to the materials at Calaveras; and there is reason to think that the coefficients found at San Pablo would apply approximately to the Calaveras materials.

---

* *Minutes of Proceedings*, Inst. C. E., Vol. CXCIX (1914–15), p. 233.
† *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 297.

What then is the explanation of the fact that the Calaveras Dam slip indicated a coefficient of 0.2 while similar materials in the test apparatus show a coefficient of 0.5—two and one-half times as much?

The answer seems to lie in the fact that in the course of construction at Calaveras, before the dam was very high, the construction pool in the center of the dam was sometimes quite wide; so that at some levels the greater part of the width of the dam was composed of fine-grained core material. Afterward the proportion of solid fill was increased and the width of core reduced, but the effects of the wide pool may have been permanently left in layers of core material extending far out under the more solid parts of the toes.

It seems probable that unstable core material placed in this way furnished the lubricant that facilitated and made possible the slip in the dam.

SECTION OF DAM REQUIRED WITH CORE MATERIAL CONSIDERED AS A FLUID.

At Calaveras, the toe material was slightly heavier per cubic foot than the core material. At San Pablo, with fragments of porous sandstone rock predominating in the toes, there was scarcely any difference. With harder material like the glacial drift of the Eastern States, the toe material would be considerably heavier.

For the purpose of a first rough calculation, assume that the weights per cubic foot of toe and core material are equal, as they are at San Pablo. If a coefficient of friction of 0.5 is assumed, each toe must weigh twice as much as the pressure exerted by the core. The pressure exerted by the core is $\frac{1}{2}\ wh^2$ and the weight of the toe to balance it must be wh^2. To produce this weight, a uniform outer slope of 2 to 1 will suffice. In addition, a top width equal to the maximum width of core must be used. If a factor of safety of 2 is required, the outside slope must be made 4 to 1, but in view of the records of slips in actual dams, it may well take a higher factor of safety. A slope of 5 to 1 will give a factor of safety of 2.5 and a slope of 6 to 1 will give a factor of 3. Where toe material is considerably heavier than the core, as would be the case with harder and heavier rocks, the slopes could be reduced in proportion to the increased specific gravity without reducing the factor of safety. Thus, with toe material 20% heavier than core material, a slope of 1 to 5 would allow a factor of safety of 3. Very few hydraulic dams have been built with sections as large as this

line of thought suggests. The Gatun Dam at Panama heads the list, and is even larger.

A great many cubic yards are involved in such a large section, but if the work is done cheaply enough per cubic yard, it may be economical to use the extra volume. Safety can be secured in this way; and it may be that this is the best procedure to follow.

Dimensions of a Number of Dams.

To see what these slopes would call for in the way of section in comparison with earth dams that have been actually built either by the hydraulic method or as dry fill, the following comparison is made. Assuming a freeboard of one-tenth the greatest depth of water, H, and a top width of 0.25 H and uniform slopes, the cross-sections of dams in terms of the greatest depth of water would be as follows:

Slope.	Volume.
3 to 1	3.9 H^2
4 to 1	5.1 H^2
5 to 1	6.3 H^2
6 to 1	7.5 H^2

The actual dimensions of a number of dams are given in Table 2. Rock-fill dams are not included, but rock fill forms some part of a number of dams in the list. No dams holding less than 64 ft. of water are included.

The Necaxa Dam slipped, but was afterward rebuilt on the original section. The Big Meadows Dam is being raised with an enlarged section.

Increasing the Grain Size of Core Material.

The second way of increasing stability is to use core material that will consolidate more rapidly and thoroughly. There is only one way to insure this; that is to increase the grain size of the material allowed to remain in the core. With pools and water quantities actually used in the dams known to the writer, particles smaller than 0.001 mm. and perhaps up to 0.002 mm. have been wasted. Everything larger has gone into the dam.

In some cases, an effort has been made to secure completeness of deposition of these fine particles to avoid waste and to increase the yardage accounted for in the dam.

TABLE 2.—Dimensions of a Number of Earth Dams That Have Stood Successfully.

* Hydraulic fill, wholly or in large part.

To increase the effective size of core material, it is necessary to increase the limit of size of particles to be wasted. This can be done by narrowing the pool or by increasing the quantity of water passing it (see Figs. 3, 8, 9, and 10). On one occasion at San Pablo, to test this out, the toes were allowed to increase in height for a time without raising the pool. This was continued until the pool almost disappeared. Hardly more than a muddy creek remained in the middle of the dam. The core became comparatively narrow and much coarser in grain size. The effective size was increased to approximately 0.01 mm. Finer particles were all wasted. In other words, the core material was, say, five times as great in grain size. It had, therefore, twenty-five times as great draining capacity, and only one twenty-fifth of the capacity to hold water by capillarity.

Material placed in this way had a much better chance of drainage; first, because the core was narrower and there was less water to be

FIG. 8.—SAN PABLO DAM, SHOWING MAXIMUM WIDTH OF CENTRAL POOL.

FIG. 9.—SAN PABLO DAM, SHOWING ORDINARY WIDTH OF CENTRAL POOL PRODUCING CORE MATERIAL 0.002 MM. IN SIZE.

FIG. 10.—SAN PABLO DAM, SHOWING CENTRAL POOL GREATLY REDUCED IN WIDTH FOR PURPOSE OF INCREASING GRAIN SIZE OF CORE MATERIAL. IT WAS PUSHED TO A NARROWER WIDTH THAN SHOWN.

removed; second, because the water had a shorter distance to go; and third, because, other things being equal, the water would get away twenty-five times as fast. After a few weeks of operation in this manner, the work was stopped temporarily, which gave an opportunity to examine the deposited core material. After only a few days it became hard enough to walk on, many times more solid than ordinary core material.

In one other respect this coarse-grained puddle differed from ordinary puddle. There was a small relative range in its grain sizes. The fine particles were eliminated, and the volume of puddle produced was reduced, but there was no very great change in the quantity and character of the coarser particles. These coarser particles constituted the whole mass of the coarse-grained puddle. With ordinary puddle, they were mixed with a large additional volume of fine-grained stock. The grains in the coarse-grained puddle were thus more nearly of the same size, and it followed that, other things being equal, the percentage of voids was greater. This was found to be the case in the test at San Pablo, and after the material had become hard and stable, it had a percentage of voids that would have indicated lack of stability in ordinary stock. This is an illustration of the fact that voids used as an index of stability can only be properly compared for the same kind of stock.

If this method of increasing the grain size of core material was to be followed throughout the construction of a dam, obviously there would be two results. First, a great deal of fine material would be wasted. The quantity would depend on the quantity of such material in the stock used. In the natural course of events most of this would be deposited harmlessly on the bottom of the reservoir. Second, a dam built in this way would be much more stable but theoretically not quite water-tight. There would be an appreciable amount of seepage through core material of this grain size.

The amount of seepage loss may be estimated approximately. Assuming that the laws of flow are the same as they are in the finest sand to which experiments have extended, it was estimated that at the San Pablo Dam if the whole core material could be made 0.01 mm. and if the remainder of the dam had contributed nothing to tightness, the theoretical rate of seepage would be 280 000 gal. per day. The loss of this quantity of water would not be a serious drain on the supply,

if it adds to stability. Practically, as is known from filter experience, considering the core material as a filter, it would soon silt up and become water-tight.

As a practical proposition in dam construction, core material having a grain size of 0.01 mm. is to be accepted as sufficiently fine from the standpoint of water-tightness. This size of 0.01 mm. is not given as a precise limit. It may be that still coarser material would give sufficient tightness or that finer material would drain sufficiently. The size is mentioned because it is the size of material that was actually found possible to produce at the San Pablo Dam by reducing the dimensions of the pool to a minimum, and because other considerations suggest that it may be suitable.

The question remains as to whether a dam in which the pool and water quantities were adjusted so as to hold the effective size of core material at 0.01 mm., or at some other selected limit, and in which the core material was never permitted to become very wide, would consolidate itself as the dam increased in height to an extent that would eliminate lateral pressure of core material.

It is the writer's idea, that a dam built in this way would certainly be more stable and safer than one in which the core material contained an additional quantity of finer particles.

This thought is similar to an idea expressed by D. C. Henny, M. Am. Soc. C. E., who stated:*

"Probably the nearest approach to a perfect core of great thickness which can be hydraulicked, is one composed of fine sandy silt, such as is generally found in the arid West, having little cohesiveness, good self-drainage qualities, becoming hard and solid after a short time, and yet being, if not perfectly, at least practically water-tight."

Mr. Henny's description may be taken as an accurate description of the writer's idea of 0.01-mm. material. It certainly does not apply to 0.002-mm. material. Mr. Henny's other propositions in regard to fine core material such as is ordinarily used, are believed to be well founded.

The Use of Rock Fill.

In building hydraulic-fill dams, the débris above the solid rock has been most easily worked and extensively used. Such débris is frequently fine in grain size, and its use may result in an excess of core

* *Transactions*, Am. Soc. C. E., Vol. LXXIV (1911), p. 82.

material and a deficiency of toe material. To correct this tendency, rock fill has been added to the toes of a number of dams.

The rock fill has usually been placed as dry fill; that is to say, by blasting, steam shovel, and cars or carts. The cars or carts run on the toes of the dam and deposit material at the same time that the hydraulic process is being used to fill the interior.

At the San Pablo Dam (see Figs. 11 and 12), a similar result has been reached by handling the rock after blasting by the hydraulic method. Open flumes were used with a flow of from 15 to 20 cu. ft. per sec. A 6% slope was necessary as long as wooden flume bottoms were used. With steel flumes, equally favorable results were obtained with a 4% slope. About 3 000 cu. yd. per day were placed, on an average. Pieces of broken rock up to 1 cu. ft. in size were handled under these conditions. By blasting the hardest rock available, it was possible to get material for fill that contained relatively few fine particles, and all of the small quantity of very fine material was wasted. Large additions to the toes of the dam were made in this way.

Working a quarry with a high face, it was possible to throw down great quantities of material in one large blast, and to wash many thousands of yards into the dam from a single position of monitors and flumes. The economy resulting from operating so long in one place, as compared with moving the equipment all over the hillside to pick up scattered and relatively thin deposits of débris above the rock, turned out to be fully equal to the additional cost of rock excavation; and rock fills, built in this way, cost no more per cubic yard than fill made from débris.

On the other hand, the fill made in this way is believed to be heavier, and to have a higher coefficient of friction which gives it additional value as toe material. The practical methods of handling rock fill were worked out by Mr. Hawley and D. W. Albert, Assoc. M. Am. Soc. C. E.

Quicksand Conditions in Dams.

When a granular material has its pores completely filled with water and is under pressure, two conditions may be recognized. In the first or normal case, the whole of the pressure is communicated through the material from particle to particle by the bearings of the edges and points of the particles on each other. The water in the pores is under no pressure that interferes with this bearing. Under such conditions,

the frictional resistance of the material against sliding on itself may be assumed to be the same, or nearly the same, as it would be if the pores were not filled with water. In the second case, the water in the pores of the material is under pressure. The pressure of the water on the particles tends to hold them apart; and part of the pressure is transmitted through the water. To whatever extent this happens, the pressure transmitted by the edges and points of the particles is reduced. As water pressure is increased, the pressure on the edges is reduced and the friction resistance of the material becomes less. If the pressure of the water in the pores is great enough to carry all the load, it will have the effect of holding the particles apart and of producing a condition that is practically equivalent to that of quicksand.

An extra pressure in the water in the pores of such a material may be produced by a sudden blow or shock which tends to compress the solid material by crushing the edges and points where they bear, or by causing a re-arrangement of particles with smaller voids. An illustration of this can be seen in the sand on the seashore. Such sand, comparable to dune sand in size, is usually found to be saturated with water for a certain distance above the water level. This condition is maintained by capillarity. If a weight is slowly placed on this saturated sand, there is a slight settlement, the grains of sand coming to firmer bearings, and the weight is carried. A sharp blow, as with the foot, however, liquefies a certain volume and makes quicksand. The condition of quicksand lasts for only a few seconds until the surplus water can find its way out. When this happens the grains again come to solid bearings and stability is restored. During a few seconds after the sand is struck, however, it is almost liquid, and is capable of moving or flowing or of transmitting pressure in the same measure as a liquid.

Fine-grained sand in which this condition exists is called quicksand. The properties of quicksand are well known. Fine-grained sand saturated with water and then mixed with an additional 5% of water acts practically as a liquid. It will flow through small orifices or in a pipe at a 5% slope. The sand in a mechanical filter in process of washing is a typical case. When the sand is drained, in the filter, it forms a bed as hard as any sand bed. When subjected to a reverse current of water strong enough to lift it slightly, however, the volume is increased by perhaps 5%, and it becomes liquid. An object can

FIG. 11—EXCAVATING ROCK AT SAN PABLO DAM BY HYDRAULIC JET, AFTER BLASTING.

FIG. 12.—PLACING ROCK HYDRAULICALLY IN SAN PABLO DAM, FRAGMENTS UP TO 1 CU. FT. BEING HANDLED BY THIS METHOD.

then be pushed through it with scarcely more resistance than would be offered by a liquid of high specific gravity.

The conditions that control the stability or lack of stability in quicksand may also control the stability or lack of stability of materials in dams.

The puddle clay core of an hydraulic-fill dam is physically like quicksand, but with particles one hundred times smaller in diameter and a million times smaller in weight. It has the instability of quicksand in full measure and it retains it for a long time, or perhaps indefinitely.

With the coarse-grained part of an hydraulic-fill dam, that is to say, with rock toes, there may be also, at times, a similar condition. Generally speaking, it would be expected that such coarse-grained materials would have sufficient drainage to let out surplus water and prevent the possibility of an excess sufficient to destroy its stability. With hard-grained materials from glacial drift of New England and the Northern States, it is hard to conceive of a lack of drainage in gravel that would permit the accumulation of an excess of water. With the softer materials of the Pacific Coast, however, the conditions may be different. In the first place, these soft rocks by partial crushing under pressure produce fine material which tends to fill the remaining spaces and to reduce the drainage capacity.

On the other hand, each increment of loading applied to soft-grained material produces a certain compression and settlement; and with it a reduction in voids. This may happen to a toe of soft rock on the up-stream side of a dam against which water is being stored during construction. There is first an open condition with ample voids and ample drainage. As the dam is built higher, pressure increases; there is compression and reduction in porosity. Each additional increment of loading and compression means that a certain quantity of water representing the difference between the old voids and the new voids must be expelled. As long as the material remains sufficiently pervious to carry off this excluded water, the process of compression is harmless. The surplus water is pushed back into the reservoir and stability is retained. There may come a time, however, when the compression goes forward so rapidly that the surplus water cannot be carried off fast enough. When that point is reached (if it is reached), there will tend to be an excess of water in the interstices

and that excess will transmit some of the pressure that was before carried only by the bearings of solid particles, and the frictional resistance of the material will be less, and perhaps much less, than it was before.

The thought has occurred to the writer, in looking at the material that slid in the Calaveras Dam, that something of this kind may have happened on a large scale—800 000 cu. yd. of fill flowed for a brief space, and then became solid. It was, in fact, so solid that in examining it afterward, by samples and by borings, it was difficult to see how the material could have flowed—as it certainly did flow.

It may be that after the first movement there was some readjustment of the material in the toe which resulted in producing temporarily this condition of quicksand, and which destroyed for a moment the stability of the material and facilitated the movement that took place.

This will not account for the initial movement; but the initial movement of some part of the material might result in accumulating pressure, first on one point, and then on another, successively, as the early points of concentration were liquefied and in that way a condition comparable to quicksand in a large mass of material may have been produced.

Summary.

To summarize briefly the points that the writer has attempted to make and to apply them practically to dam construction:

1.—It is not well to build an hydraulic-fill dam of material of which any large percentage consists of clay or of particles less than 0.01 mm. in diameter; and in general all such smaller particles may well be wasted and excluded from the dam.

2.—By reducing the construction pool to a minimum, and by controlling it and the quantities of water used for sluicing, the core material may be held to a certain degree of coarseness by wasting all smaller particles. An effective size of 0.01 mm. may reasonably be sought.

3.—To study by borings the actual consolidation of the material, and to adjust the construction of the upper parts of the dam to the demonstrated condition of that which lies below.

4.—To make the toes large enough to resist with an ample factor of safety the whole pressure of the core material as a liquid until there

is demonstration of the solidification of the core to a point where horizontal pressure is eliminated.

5.—To increase the weight and solidity of toes by the use of rock fill, placed hydraulically or otherwise.

6.—Stability is increased by compactness. It is worth while to watch voids closely, and to make every effort to hold them at a minimum. The extra weight is advantageous, but security against compression and re-arrangement with resulting temporary quicksand conditions, can be best reached in this way.

A strict application of these principles may reduce the number of hydraulic-fill dams that are built by eliminating that method of construction from consideration where the available material contains too many very small particles. It may also increase considerably the volume and cost of those that are built. It would seem, however, that following them to a logical conclusion, with such testing as can reasonably be done, will result in eliminating present uncertainties and in putting a most useful method of dam construction on a definite and safe basis.

DISCUSSION

Mr. Curtis.

C. E. CURTIS,* M. AM. SOC. C. E. (by letter).—This interesting and instructive paper dwells on two important elements in hydraulic-fill dam construction, core material and toe material, discussed with greater care and in greater detail than the writer has yet seen. The summary is valuable because it states, briefly and clearly, important facts well worth consideration by any one engaged in building hydraulic-fill dams. It makes available, in a few sentences, facts that otherwise might require much reading and investigation to obtain. The important points are brought to the reader's attention and the things necessary to bear in mind for a successful dam built by the sluicing method are indicated.

Two important features to be carefully considered in every hydraulic-fill dam are the fine, plastic, primarily impervious, unstable core and the coarse, stable, pervious, supporting outer embankment, spoken of by the author as the toe. It is essential to have a water-tight core and equally essential to provide sufficient coarse material to hold the core in place and give stability. The whole secret of hydraulic-fill dam construction, in the writer's opinion, is the proper handling of these two features without making either excessive and, at the same time, obtaining the desired result, namely, a tight and safe structure. The details of handling these features are, of course, necessarily different in every operation, because of the varying conditions, but the principle is the same always.

The writer was much interested in the description of the pipe tests used to determine the solidity and character of core material, because of the similarity in both methods and results to those obtained in his own experience. He found that 30 or 35 ft. was about the limit that two men could push a 1-in. pipe down into the soft material of the core, and that 60 ft. was about the limit the same pipe could be driven by using hand hammers. Samples taken from the pipe were quite uniform and the most satisfactory of any obtained. There was always the feeling, however, that a sample obtained in this way was more compact, due to the manner of taking it, than the material really was in the dam, but samples so taken are the best that can be obtained, as far as the writer's experience goes.

The author states that he found it necessary to stop sluicing in order to make pipe tests. The writer has known of instances where such tests were usually made while sluicing was in full progress, without any trouble or inconvenience, the work being done by men on a raft.

In a locality where fine material predominates and it is difficult to get coarse material in large quantities, it might become necessary

* Ithaca, N. Y.

to waste the very fine particles of the core material in order to secure compactness, but, on the other hand, in a locality where coarse material predominates, as it does in some places, it is perhaps not always necessary to do this, but the finer the core material the more necessary and difficult it becomes to hold the fine particles where they belong. It can be done successfully only by providing an adequate mass of coarse material well and carefully placed. Mr. Curtis.

Some years ago the writer was in charge of an hydraulic-fill dam where great care was exercised to retain all the fine material possible in the core, as it was thought to be necessary for tightness and would also add to the volume in the embankment. This dam, more than 90 ft. high, was built without any slips or constructional mishaps and is unusually tight with little if any seepage through it. There was, however, an abundance of both coarse and fine materials advantageously located for sluicing so that the proportions could be easily controlled. The work referred to is the Quemahoning Dam of the Cambria Steel Company, near Johnstown, Pa.

Fig. 13 shows a cross-section of the completed dam with the general sub-divisions or zones of material indicated approximately as the dam was built. The late Frederic P. Stearns, Past-President, Am. Soc. C. E., was the Consulting Engineer for the dam; Joseph Morgan, Consulting Engineer for the Cambria Steel Company, was Consultant on the dam and the pipe line; and John W. Gocher, Chief Engineer of the Cambria Steel Company, was Chief Engineer of both. The writer had charge of the construction of the whole development including both the dam and the pipe line. Fig. 13 contains several brief statements of facts pertaining to the dam, and the following notes in regard to the pipe line, which was built at the same time and is a part of the development, are pertinent.

The distance from the dam to the works by pipe line is 14 miles; the pipe is 5 ft. 6 in. in diameter and its total weight is 13 000 tons; it crosses Stonycreek River thirteen times, passes through five tunnels aggregating 9 000 ft. in length and the daily flow is from 75 000 000 to 90 000 000 gal. The catchment area is 92 sq. miles and the flooded area 900 acres.

This dam, 93 ft. high above the natural surface of the valley, was built with flat slopes of 4 to 1 for the lower and 3 to 1 for the upper half of the embankment; both the up-stream and down-stream slopes were the same. The width of the spillway is 250 ft., the maximum calculated flow over which is 11 800 000 000 gal. per 24 hours. The dam is 950 ft. long on top and contains about 600 000 cu. yd. of material, of which more than 500 000 cu. yd. were sluiced. The two dikes (marked *d*) one at each toe, were built by team and scraper of material taken from the middle third of the area covered by the dam. A certain limited quantity of material on the top was placed by hand

Mr. Curtis.

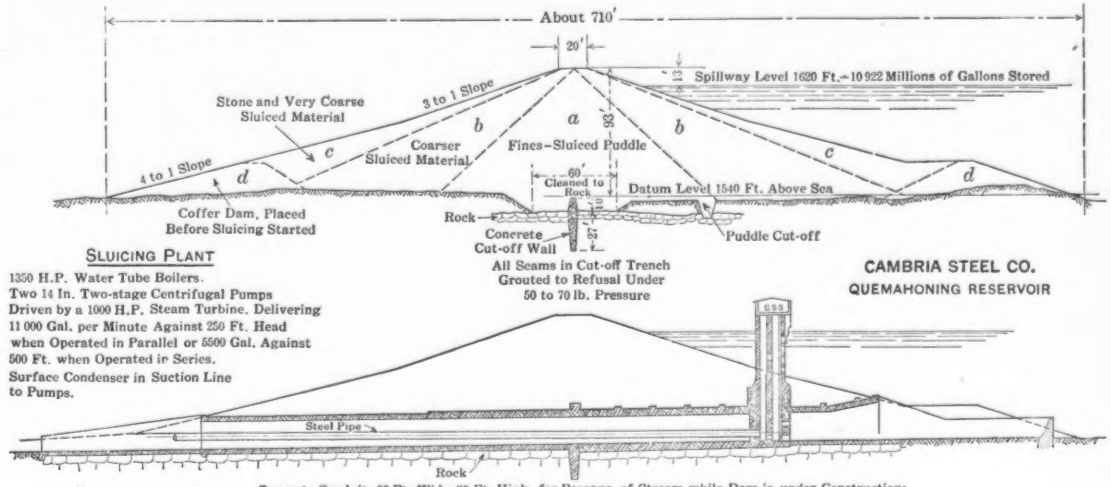
in the usual manner, all other material having been sluiced. The sides of the valley were about 200 ft. higher than the top of the finished dam, so there was sufficient elevation to secure the desired grade for sluicing and, at the same time, discharge all the material on the dam without rehandling. This condition made sluicing comparatively simple. The largest rock carried by the sluices was about 1 ft. square by 3 ft. long, and a depth of water of between 6 and 8 in. was sufficient to transport rocks of this size on a 6% grade. One side of the valley was shale rock in ledge formation with only from 4 to 6 ft. of glacial drift on top, the other side being composed of a heavy deposit of glacial drift and clay with many stones and boulders mixed through it. It was not difficult, therefore, to get nearly any desired proportion of coarse and fine material.

The shale was drilled and shot with a light charge of dynamite so as to shake it up a little without throwing it down. This made sluicing easier and, by so doing, it was quite practicable to carry a 40-ft. vertical face in the sluicing pit. It also hastened the work to shoot the clay. In either material, a very small crack was all that was necessary to give the water a chance to do its work.

All material was conveyed to the dam in wooden sluices, 24 in. wide and 18 in. deep, built on a 6% grade, and placed so that they discharged the material at the extreme outer edges of the embankment on both up-stream and down-stream toes. The very coarse material, composed of large stones and rock, remained where it was discharged from the sluice-box, while the intermediate grades, between very coarse and very fine, were deposited at varying distances from the sluice, depending on the quantity of water used in sluicing and the elevation of the central pool for controlling the deposit of core material. The fine sands produced by the sluicing would build up on a very steep slope at the edge of the pool for a height of 2 or 3 ft., then slough off and slide into the soft core material. This operation was repeated to a greater or less degree during the whole sluicing period. The central pool was usually from 1½ to 2 ft. deep, and at these depths it was large enough, for two-thirds of the height of the dam, to allow quite complete sedimentation so that there was very little loss over the waste weir provided to carry off the sluicing water.

The width of the core at the base was a little less than one-third the total width of the section, decreasing as the height increased. The proportions gave room for a sufficient bulk of coarse material to hold the core in place. It is the writer's opinion that this thickness of the core is greater than was necessary and in the future he would be inclined, under like conditions, to reduce its cross-section materially on the theory that less thickness is ample for water-tightness and that the increased quantity of coarse material is an added security against sliding. Under some conditions and in some locations, depending

Mr. Curtis.



Concrete Couduit, 30 Ft. Wide 20 Ft. High, for Passage of Stream while Dam is under Construction; Upper End Afterward Closed by Gate-house and Pipe Laid Through it.
13 250 Cu. Yd. Concrete in Conduit.

FIG. 13.

Mr. Curtis. largely on the kind of material, it might be best to steepen the slopes, omitting the 4 to 1, for instance, and using 3 to 1 for the full height of the dam. A steeper slope than the latter does not seem to be desirable.

In support of this statement the writer will mention the Salt Lick Dam, of the Johnstown Water Company, which has 3 to 1 slopes both up stream and down stream. It was built at the same time and in the same manner as the Quemahoning Dam. Frequent pipe tests were made of the core, as the work progressed, in order to obtain some idea of the solidity of the material. As mentioned previously, from 30 to 35 ft. was the average depth reached without driving, and 60 ft. by driving. At corresponding depths the samples were usually the same and about the consistency of stiff putty.

No tests were made for fineness of the core material, but chemical analyses and determinations of specific gravity, the results of which are given in Table 3, were recorded.

TABLE 3.—ANALYSIS OF CORE MATERIAL, QUEMAHONING DAM.

No.	Percentage of loss on ignition.	Percentage of iron peroxide.	Percentage of alumina.	Percentage of silica.	Percentage of calcium carbonate.	Percentage of magnesium carbonate.	Specific gravity.
39	8.06	7.08	17.36	61.62	Lime	3.10	2.45
40	7.70	8.34	13.08	68.52	0.68	1.15	2.63
41	6.99	8.24	14.68	67.56	0.76	1.41	2.55
42	5.16	5.96	10.84	76.52	0.36	0.68	2.44
43	7.14	6.96	13.44	70.52	0.60	0.82	2.50

It should be noted that the specific gravity of the material varies as much as 8 to 9%, and is less than the result given by Mr. Hazen, which was 2.65.

It may be of interest to give the results of the analyses of two samples of sluiced material from the Sánta Amoro Dam, São Paulo, Brazil, sent to the writer by the late James D. Schuyler, M. Am. Soc. C. E., in 1918. The analyses are given in Table 4.

TABLE 4.—ANALYSES OF SLUICED MATERIAL, SÁNTA AMORO DAM.

No.	Percentage of loss on ignition.	Percentage of iron peroxide.	Percentage of alumina.	Percentage of silica.	Percentage of calcium carbonate.	Percentage of magnesium carbonate.	Specific gravity.
21	13.82	10.85	36.08	38.68	None	0.22	3.94
22	14.70	8.68	37.80	37.20	"	0.17	3.90

Mr. Curtis.

There is a marked difference between the analyses of the material in the Quemahoning Dam and that from South America. The extremely high specific gravity of 3.90 and 3.94 is, the writer assumes, rather unusual, although sluiced material from the Nuunau Dam, Honolulu, Hawaii, showed a specific gravity of 3.11. The writer is indebted to Mr. Schuyler also for this sample.

The solidity and compactness of the Quemahoning Dam may be indicated by the amount of settlement after completion. To provide for any possible shrinkage due to settlement, an additional height of 3 ft. was added to the dam. Careful levels were taken frequently along both the up-stream and down-stream edges of the top width and after a period of nine months from the date of completion, the average settlement was not more than 9 in., or less than 1% of the height. From this, it is apparent that although the core material was very soft when placed, it later became a rather compact mass of plastic clay. It is quite probable that the dry material, placed by hand on top, settled into the semi-liquid layer of core material, absorbing the water it contained, so that the whole mass became stable.

The writer has referred at some length to his own experiences with hydraulic-fill dams because the results obtained coincide so well with, and support, the author's statements. The Quemahoning and Salt Lick Dams show that dams of considerable height can be built successfully by the hydraulic-fill method.

The fineness of the core material and the size of particles that should be wasted depend very largely on the character and quantity of coarse material available. It would seem to be desirable to sluice as much of the coarse material as possible and deposit it at the outer edge of the embankment. In this way the medium grades of material are carried toward the central pool by the water, becoming thoroughly compacted in the operation, and making a firm unyielding mass with practically no settlement after completion. Throughout the construction of the Quemahoning Dam, all the area from the outer edge to the central pool was firm enough to walk on without sinking in.

From what the writer has seen elsewhere, and from his own experience, he is satisfied that where conditions warrant its adoption, hydraulic-fill dam construction is practical, economical, and a very satisfactory type of earth dam. It is a type of construction which, although apparently simple, requires close attention to details.

Mr. Chase.

RICHARD D. CHASE,* ASSOC. M. AM. SOC. C. E. (by letter).—After spending about two months at the San Pablo Dam, the writer became so impressed with the small labor and plant cost, that he thoroughly believes the hydraulic-fill method is worthy of being adopted in the East. It is perfectly true that failures of these dams have occurred, but the number of successful ones is sufficient to indicate that success

* New Bedford, Mass.

Mr. Chase. is not due to chance, and Mr. Hazen gives good theoretical and practical reasons for the failure or success of such dams.

When one observes the light soil and the soft, friable, quickly disintegrating rock which are the only available materials at San Pablo and Calaveras, one can realize that the hydraulic-fill method would be most applicable to the heavy glacial drift of the northeastern part of the United States.

With the present unsatisfactory labor market, particularly for heavy manual labor, any method of construction that will decrease the number of men on a piece of work deserves more than usual consideration. It was hard to believe that the half dozen men on the dam and the few on the hillside were putting in 100 000 cu. yd. per month. There was also a comparative absence of expensive plant. It is true the situation was most favorable, with the borrow-pits above and directly adjacent to the ends of the dam—an advantage hardly probable in the East—but even with preliminary handling the advantages are so obvious that serious consideration should be given to the hydraulic-fill method for any earth dams.

The writer believes that this paper will clarify the theory and practice of the hydraulic-fill dam so that it will not be treated as a doubtful experiment, with the chances of failure outweighing its obvious advantages, and that by following the theory laid down one can feel that he is proceeding along sure and definite lines, with a method provided for testing the results obtained so that the chance of failure is eliminated.

Mr. Elliott. G. A. M. ELLIOTT,* M. AM. SOC. C. E. (by letter).—This paper is timely in that it brings to a head and assembles, where it is readily accessible, the results of present experience in hydraulic-fill dam construction. The fundamentals of this type of dam, so clearly set forth by the author, have too often received little consideration. This method of dam construction is attractive on account of its comparative cheapness, and has been adopted for that reason in some instances, when, with the same materials, another construction method would have been more suitable. The hydraulic-fill dam is not to be regarded as a general type, to be built under all conditions of earth-fill, but should be used only when all the facts make it advisable.

It seems to the writer that if the proper relation between width of toes and core is maintained, the grain size of the core material will automatically take care of itself. For instance, if the material used is of a hard rock base, such as a gravel deposit, it will probably not break up under handling sufficiently to give a preponderance of very fine core particles, and naturally a narrow core and comparatively wide toes will result. An example of this is to be found in the Paradise Dam near Chico, Cal. The material in that locality is of volcanic

* San Francisco, Cal.

Mr. Elliott.

origin, and some difficulty was experienced in obtaining a sufficient quantity to insure an impervious center. During construction the drainage through the toes was of such proportions as to be alarming to one not familiar with the hydraulic method. This dam has been completed and in use for three years with excellent results so far as tightness is concerned. In the case of softer materials which, in handling, will break up to such an extent that an excessive quantity of fines is delivered to the "core-pond", the wastage of the surplus puddle necessary to maintain a narrow impervious center will result in automatically discarding very fine particles. A core-pond width of not more than 20% of the total thickness of the dam at all elevations is sufficient for water-tightness, is not too narrow to interfere with ease of construction, and, with proper care in distribution, there is no danger of tongues of coarse material encroaching on the impervious area. To hold to this width in dams built with the comparatively soft materials which must sometimes be used, will necessitate wasting considerable material. This increases the construction cost. It is difficult to persuade engineers of the necessity for wasting material which has cost a great deal of money to break down and transport a considerable distance. Until this fact is fully recognized, failures of hydraulic-fill dams will continue to occur.

It is important not to exceed the predetermined boundaries of the core-pond at all stages of construction. When the fill is carrying an excess of core material there is a tendency to retain all of it, on the theory that even though the clay overlaps the dry toe area, it can be displaced later by the use of other material carrying an excess of rock. In some cases this displacement is attempted by dumping dry fill along the edges of the pond. At best, it is uncertain just what happens under this treatment. It is the writer's opinion, after some experience with the latter method, that although, of course, the dry material does displace a certain quantity of liquid clay, the character of the resulting fill is not as good as the dry banks laid down by sluicing. If clean rock is used, the interstices are filled with liquid clay, and the hydrostatic pressure may be transmitted through the new fill to the original dry banks. The new fill is lubricated, and if the internal pressure is sufficient to move the dry toe, the mass of lubricated rock, instead of adding stability, will move almost as readily as the core. If a mixture of earth and rock is used there may be danger of masses of this material trapping large pockets of clay, which, in effect, provides points of lubrication. Well-drill explorations of an embankment made by combined hydraulic placing and dry dumping will not give complete data, as the operation of boring the well grinds up the fill into small particles. Even if this character of exploration does indicate that the coarse material has apparently displaced the clay, it tells nothing in regard to the fact that the voids in the rocks may be filled with liquid core.

Mr. Elliott.

Exploration by borings in the up-stream toe of the Calaveras Dam made during construction indicated a solid fill in locations in which the core had been replaced by dry fill. In the light of later events, the writer is convinced that the mass of coarse fill, placed by wagon in and along the edge of the core-pond, was permeated by the semi-liquid clay core, and that it added little or nothing to the stability of the structure. The action of the down-stream toe, which, although not as thick as the combined up-stream toe (placed by hydraulicking and wagon), was built of dry material dumped from cars on trestles, bears out this conviction. This embankment was built up vertically, that is, the inner face did not encroach on the core-pond to any great extent with increased elevation, and the material was not placed in the core itself for the purpose of forcing it back. Under this method there was no opportunity either for trapping the clay masses or for the voids in the dry bank to be filled with wet core material. In spite of its smaller section, this embankment did not move horizontally. Mr. Hazen's quicksand theory would apply directly to that portion of the dry embankment built by displacing the core by dry dumping.

A semi-hydraulic-fill method has been used with success on the Pacific Coast in cases where the material available consisted of soft rock which would not lend itself to economical spreading and rolling and would break down badly with water transportation. Briefly, the material is transported in cars and dumped on the up-stream and down-stream embankments, leaving a predetermined distance between for the core. This space is filled with water, and a pump mounted on a barge is used to jet down the exposed inner surfaces of the banks. By using this plan the core is under absolute control at all times. The dry banks are loosely placed, and consolidation occurs in time through natural settlement. In the case of small dams which might be built in one season and filled immediately thereafter, there might be some objection on the score that the embankment had not consolidated sufficiently, but on large dams requiring several years to construct the settling action due to rain and time would offset this feature. The down-stream embankment of the Calaveras Dam was built in this manner, and showed no signs of settlement beyond two years after placing. The Haiwee Dam built by William Mulholland, M. Am. Soc. C. E., in Owens Valley, California, was successfully constructed in this way.

Mr. Howells.

J. M. HOWELLS,* M. AM. SOC. C. E. (by letter).—Engineers are indebted to the author for an instructive analysis of the fundamental principles involved in hydraulic-fill dam design and construction and as a contribution to the discussion, the writer presents only minor variations of viewpoint from those taken by Mr. Hazen. One of these differences is in the matter of homogeneity of core material, for the

* San Francisco, Cal.

writer has noted that almost invariably toward the finish of a dam, as the top approaches the form of an elevated canal, the construction water flows so rapidly that it carries off core material needed for water-tightness. Also, at this stage of the work, as the hydraulic fill is delivered at both the up-stream and down-stream faces, it has been difficult to prevent the deposit of coarse porous sand "tongues," which often reach entirely across the central pool, thus tending to loss of water-tightness. Mr. Howells.

The writer wishes to present one phase of Mr. Hazen's paper concerning which confusion on the part of the members of the Society seems to prevail, that is, the simple question as to what constitutes an hydraulic-fill dam.

At a meeting of the San Francisco Section of the Society, a committee was appointed, composed of Mr. Hazen, C. E. Grunsky, M. Am. Soc. C. E., and the writer, as Chairman, to "formulate and present to the Section, the definition of the term 'hydraulic-fill dam' ".

As this type of dam is a Western development, it was considered appropriate that the San Francisco Section should presume to appoint a committee to formulate this definition. The report of that committee follows:

"*Definition of an Hydraulic-Fill Dam.*—The hydraulic-fill dam method of constructing earth dams implies a conveyance of material to its place in the structure by flowing water, but the material may be brought to the structure by mechanical means, providing it is properly washed and segregated while it is in the process of being deposited.

"Any dam constructed throughout by this method is an hydraulic-fill dam.

"The method further implies more or less separation of the material into two distinct classes, each deposited in definite locations within the cross-section of the dam—the coarsest, most gritty, and porous conveyed and deposited by running water and constituting the outer portions of the dam, to secure stability; and the finest and most water-tight material deposited under standing water and constituting the central portion, insuring water-tightness.

"Whenever an appreciable part of a dam is built by the dry-fill method and a part by the hydraulic-fill method, the structure is no longer to be classed as an hydraulic-fill dam, but is a combination structure—a loose rock dam with hydraulic-fill core, a dry-fill earth dam with hydraulic-fill core, etc., as the case may be."

According to this definition, the Calaveras Dam is not an hydraulic-fill dam.

In referring to the mysterious action of the material in the toes of the Calaveras Dam, its lack of stability before the accident, and and its tendency to stabilize after the accident, one might look to a fact not brought out clearly enough by the author, namely, that, as previously stated, the Calaveras Dam was in no sense an hydraulic-fill dam. It was started as such, and about 60 ft. of the base was built in

Mr. Howells.

that manner, and this part was found to be intact after the disaster. It is important to bring out this fact, as many of the technical papers have called this structure an hydraulic-fill dam.

Above the 60-ft. base, the dam was composed of a pumped hydraulic-fill core of slimes, built between toes, like dry railroad dumps, with no washing of the latter to carry away the native slimes which when wet are inherent in their masses. Neither was any apparent effort made to build these dry fills in thin horizontal layers, a practice considered as standard for earth dams other than those built by the hydraulic method. If there were any layers in these toes, they were on a slope of about 1½ to 1, and resulted from the sliding over-dump of the dry material. As this dumping of the toe material progressed, great porosity or looseness of the mass resulted, and the writer has been told on good authority that the puddle-core material often found an outlet by irregular channels through this loose dump to the faces of the structure. Thus, while settlement was in progress, lubricated planes were being arranged to take part later in the ultimate disaster.

That the slip did not take place on the down-stream face which was steeper and theoretically less stable, was probably due to its opportunity for drainage. On the up-stream face, both the reservoired water and concrete facing interfered with such drainage. This, together with the sloping structural planes of deposit (already in movement as they successively settled), must explain to a great degree the point mentioned by the author in his endeavor to account for the low coefficient of friction in otherwise fairly stable material.

Had the Calaveras Dam been a true hydraulic-fill dam, its toes would have been brought up in thin vertical increments from which all slimes would have been washed and stability insured.

The writer agrees with the author on the possibility of too broad a core being left where the true hydraulic-fill section ended, and that this might add to the tendency of the face to slide or to transmit pressure dangerously close to the faces; for in an hydraulic-fill dam of the height proposed, stability could be insured only by great width of base of both toes. This is shown by the accepted formula in which coefficient of friction and weight of mass rather than percentage of voids controls.

In this connection there is grim comfort to the builder of hydraulic-fill dams or any of their variations, namely, that they are never so weak as during construction, for at that time they are virtually two slender dams storing between them a heavier-than-water fluid. Therefore, if they stand under these conditions, they have been tested with a liberal factor of safety and are ready to assume their greater responsibility of storing a great volume of water.

As for the author's suggestion to waste core material finer than a given size: It often happens that this fine material is needed as against the porosity of the river bed itself above the dam, and in cases of dam

construction within an area of about 200 000 sq. miles in the Northwestern United States, where porous lava flows cover almost the entire country, this waste would be useful. The Big Meadows Dam is within the area mentioned, and its successful construction and seven years of operation argue for the special adaptability of the hydraulic-fill dam to such foundation conditions. Mr. Howells.

The author places a great deal of stress on his void theory and, within the limitations which he places around it, there is no doubt but that the percentage of voids in the puddle core can be studied profitably, but, after all, no reliance should be placed on the puddle core for stability. It has another office.

As to the toes of hydraulic-fill dams, voids are desirable rather than otherwise, and should add to rather than detract from the stability of the entire structure.

In the original conception of the hydraulic-fill dam it was hoped, more often than later proved feasible, to secure a gradation of material from coarse at the faces to fine in the center, similar to that described in the paper* by the late James D. Schuyler, M. Am. Soc. C. E. This would insure greater voids toward the faces, better drainage, and less chance for water pressure as the faces of the dam are approached, and any drainage from the puddle core, or perhaps through the dam after construction, loses the possibility of destructive pressure by successively entering more and more porous beds of sand, gravel, and rock. Thus, the pressure diminishes and drainage flow begins so far within the structure as to be inert as against destructive effect. This was noticeable for its absence in the railroad-dump type of toes exemplified in the Calaveras Dam.

As to the use of rock-fill in the toes, this, at times, seems to be excellent practice and became a part of the design of the Big Meadows Dam, in the construction of which the problem of stability and watertightness presented itself in a peculiar form. That is, it was necessary to connect the central puddle core with a water-tight layer placed over the stream bed for approximately ¼ mile up stream from the dam. By first placing massive basalt rocks for stability into the proposed upstream toe, on a gritty foundation of native boulders, gravel, and sand, it was possible later to pass fine hydraulic fill through this basalt rock-fill and onward up stream to line the old river bottom and also to secure connection of this fine river lining with the puddle core of the dam.

In conclusion, the writer wishes to state that he agrees generally with the author's final summary.

D. C. Henny,† M. Am. Soc. C. E. (by letter).—The author has given with his usual clearness the reasons which render the use of very fine material in the core of hydraulic-fill dams objectionable. Dams Mr. Henny.

* *Transactions*, Am. Soc. C. E., Vol. LVIII (1907), p. 196.

† Portland, Ore.

Mr. Henny.

with such cores, however, have been built and have not failed, so far as the writer is aware, after construction had been carried to completion.

An interesting and perhaps important question is the condition of the core after several years' use. The author points out that a reduction of water content from 70 to possibly 50% may proceed by vertical settlement with relative promptness. There comes a point, however, when the movement of water through the mass becomes extremely slow, while a condition of horizontal pressure transference and lack of stability still exists. Full stability may be reached after voids have been reduced to about 40 per cent.

It was pointed out that a void reduction from 50 to 40% means that 6 cu. yd. would become compacted to 5 cu. yd. Whether such a core in a dam which periodically or permanently stores water, will ever reach this degree of compactness may well be doubted, as the repeated watering which the core receives, will permanently prevent complete consolidation on the water side, and this retarding effect may be carried far into the body of the core.

It is quite probable, however, that the down-stream side and the upper portions of the core will undergo a drying out process through slow evaporation, and thus it may be expected that the core, especially near the top, may show a condition of supersaturation on the up-stream side below the level of high water, gradually changing in a down-stream and upward direction to one of compactness.

The compacted or dryer portion must have lost volume. The resultant condition in the core of a dam like the Necaxa has never been examined by shafts, so far as the writer knows. Volume reduction may have taken place through vertical settlement, but after the water content has been reduced to some limit like 50%, it is not improbable that further drying will produce vertical cracks, and such cracks in themselves would act as drains and thereby expedite the drying process.

If a dam with an hydraulicked clay core was to store no water for a long series of years, it is conceivable that cracks might reach through the entire core, at least in the upper portion of the dam, a condition which if not immediately dangerous in view of the high power of resistance to erosion which dry compacted clay possesses, is neither desirable nor permanently safe. Such a condition may be regarded as another important objection to the use of clay in cores, at least until actual inspection of clay cores in existing dams proves the foregoing conception to be erroneous.

The writer wishes further to call attention to the effect which the rise of water against a dam with a clay core, either during the construction period or thereafter while the core is still semi-fluid, may have on the possibility of a slide toward the reservoir.

Mr. Henny.

If Fig. 14 represents the cross-section of a completed dam, of the dimensions indicated, with a semi-liquid core, and the weights of material may be assumed to be similar to those found by the author at the Calaveras Dam, as follows:

Weight of core material with about 50% water content	100 lb. per cu. ft.
Weight of material in outer sections.....	120 lb. " " "
Weight of material in outer sections when dry	110 lb. " " "
Weight of material in outer sections submerged	73 lb. " " "

then, with water in the reservoir at or below the base, the weight on the base, AB, of the up-stream toe section per linear foot of dam is 400 tons. The horizontal outward pressure of the core is 202 tons and the sliding factor is approximately 0.5.

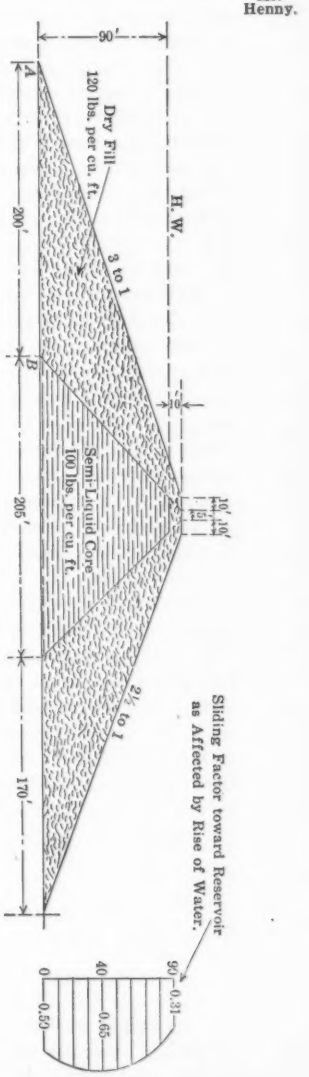


Fig. 14.

As the water in the reservoir rises there will be created a horizontal counter pressure tending toward a reduction of the sliding factor. At the same time, however, the weight on AB will become reduced through submergence of the material, tending to increase the sliding factor. The combined effect is shown for various heights of reservoir water to the right in Fig. 14.

It will be noted that the danger of sliding increases 30% as the reservoir fills to 40 ft. above the base of the dam, after which it decreases. This indicates the danger which may exist in allowing the reservoir to fill during its construction or even some time after its completion.

In the case considered, with reservoir empty, a sliding factor of 0.50 is calculated in a dam with a water slope of 3 to 1. The author argues that such a sliding factor will be obtained with a water slope of 2 to 1.

Mr. Henny. This is, however, under essentially different conditions. The difference lies partly in that Mr. Hazen bases his statement on equality of weight of toe and core material instead of the weights of 120 and 100 lb. per cu. ft., respectively, herein assumed.

The principal difference, however, lies in his assumption that the weight of the entire triangular mass in the dam up stream from the top contributes toward resistance to sliding. This can be true only if the core material, or horizontal layers of it, do not extend under the slope. Where this does occur, the author mentions for the Calaveras Dam sliding factors of 0.20 and 0.22, which are obviously average factors for the entire toe base and not the much higher factor in the toe material considered by itself, which, as the writer sees it, is controlling.

Reference in this connection has been made in a brief discussion of this problem* in which the writer argues, in connection with the Calaveras Dam, from such information as was available on the ground and as was subsequently furnished by the author, that at the time of the Calaveras slide the sliding factors in the base of the toe material may have been close to 0.7 toward the reservoir and 0.5 away from it. These values although they cannot be claimed to be accurate, due to lack of definite information regarding distribution of materials in the dam, at least explain satisfactorily why sliding took place in an up-stream and not in a down-stream direction, and that so far as information goes, 0.7 may have been approximately the coefficient of friction in the toe material.

The writer's analysis may be in error in so far as he assumes the weight on the toe base to be that of the material vertically above it. This may be reasonably correct for a dry-built dam, but in the case considered may be in error in view of the tendency of the entire outer section to slide toward the reservoir along the up-stream side of the core. To test this point a brief analysis was made of the case illustrated in Fig. 14. Neglecting the weight of the small part of the dam above the high-water line and considering only the part of the dam up stream from the vertical, *CD* (Fig. 15), the following values result:

Weight of toe section	618.3 tons
" " core "	222.8 "
Total weight	841.1 "
Load on core base 4.5×99	445.5 "
Load on toe base	395.6 "

The weight of toe material vertically above the toe base is 400 tons, so that in this case the previous assumption is practically correct, as is also indicated by the loading diagram in Fig. 15.

* *Engineering News-Record*, March 6th, 1919, pp. 487–488.

Mr. Henny.

This close equality, however, may be somewhat accidental. Submitting the case of the partly completed Calaveras Dam, before the slide, on the basis of the section shown in the writer's article previously quoted, to a similar analysis, the figures stand as follows:

Total weight of up-stream section	1 787 tons
Weight on core base	1 304 "
Weight on toe base	483 "
Weight of toe vertically above toe base	548 "

There is considerable difference in this instance. If the latter analysis is the more correct, it would seem that a large part of the weight vertically above the toe base is transferred to the core base; also that the coefficient of friction at the time of sliding may have been in excess of 0.7.

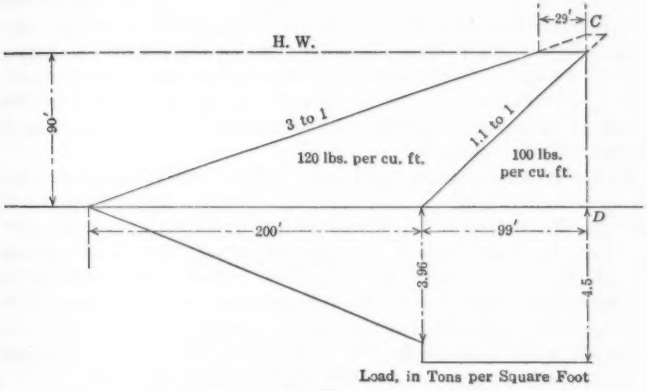

FIG. 15.

The uncertainties unavoidably involved in dealing with a structure of which the interior condition is so little known preclude the derivation of any definite friction coefficient and show the necessity of adopting some factor of safety, as argued by the author.

The author by an interesting experiment at San Pablo Dam has found coefficients of friction of 0.45 to 0.55, and for harder material of 0.70. He found further that values with pressures lower than those due to a depth of fill of 200 ft. were found to be distinctly larger, and he considers the materials at San Pablo and Calaveras as quite similar. Considering that the toe pressures at Calaveras before the slide were due to an average height of fill of less than one-third of 200 ft., there appears to be nothing in the result of the experiment disproving a possible friction coefficient at Calaveras of 0.7.

Mr. Henny.

The limitation as to fineness of material which is to form the core is obviously a measure of safety, and the author's definition of the limit is especially welcome. It is probable also that it can often be applied in construction without thereby rendering the hydraulic process uneconomical. Undoubtedly, cases will arise, however, where with an abundance of clay and intermingled coarse material a shortage of the finer particles approaching the 0.01-mm. size will occur, and that a clay core must be depended on for tightness.

Safety and economy will then combine in suggesting a far thinner core than has been commonly used heretofore. The author mentions testing out a narrow pond at the San Pablo Dam, so narrow indeed that hardly more than a muddy creek remained in the middle of the dam. The writer's experience leads him to think that under such extreme conditions the passing of coarse sand layers or lenses through the entire core is highly probable, due to changes in the material delivered from the pit—an undesirable although not necessarily dangerous result. The paddling of pond material described in connection with some dams has been practiced in the past to destroy such stratification. The writer, however, has found it to be practically impossible to mix pond material in that manner where the sand layers were of any appreciable thickness.

If a clay core must be used and sufficient graded coarse material can be sluiced to hold the core material and form the outer section of the dam, the proper solution may be a core of no greater thickness than can be hydraulicked without danger of sand layers passing through, the remainder of the clay to be wasted. The design of the Calaveras Dam is in accord with past practice, yet there appears to be no reason why a similar dam should not have been entirely tight with a core 100 ft. thick at the base instead of over 400 ft., and it is certain that with such dimensions the slide could not have occurred.

The author's conclusion that with a coefficient of friction of 0.5 in the toe material and with equality of unit weight of toe and liquid core, an outer slope of 2 to 1 will provide a factor of safety of 1, implies, as previously stated, that a liquid core in a solid mass or in horizontal layers does not extend under the slopes. If the core occupies one-third of the mass, a factor of safety of 1 under the same assumption of a coefficient of 0.5 would require a slope of 3 to 1 instead of 2 to 1, a distinction which it may be of great importance to bear in mind in view of the fact that hydraulic-fill dams, in all cases with which the writer is familiar, as well as dams with the narrowest feasible clay core, will have a considerable quantity of core material extending under the slopes.

Referring to the claims that considerations of stability require hydraulic-fill dams to be given flatter slopes than other earth dams, the writer believes that although from the previous arguments it may

be concluded that such claims are valid in the case of cores of large dimensions consisting of very fine material, they lose force where the clay core can be made thin and the material for the outer sections is reasonably coarse, and such claims appear to be entirely invalid where the core is composed of larger particles of about the limiting size of 0.01 mm. suggested by the author, since in that case the core has self-draining properties and becomes promptly as hard and stable as material in a well compacted dry-fill dam. Mr. Henny.

A. T. GOLDBECK,* ASSOC. M. AM. SOC. C. E. (by letter).—In his discussion of the measurement of pressures existing in the cores of hydraulic-fill dams, the author mentions a method now being used by the Miami Conservancy District, with a special type of apparatus developed by the writer with the collaboration of Mr. E. B. Smith and others connected with the laboratories of the United States Bureau of Public Roads. It would seem that the author has overlooked the possibilities of this method for, apparently, he is not fully informed as to the degree of accuracy to be expected from this type of instrument. Mr. Goldbeck.

For the benefit of those who are not familiar with the soil-pressure cell mentioned by Mr. Hazen and used very successfully during the past several years in the U. S. Bureau of Public Roads for measuring the distribution of pressures through granular materials, it may not be amiss to introduce at this time a short description of the apparatus, together with illustrations of its application and tests confirming its accuracy.

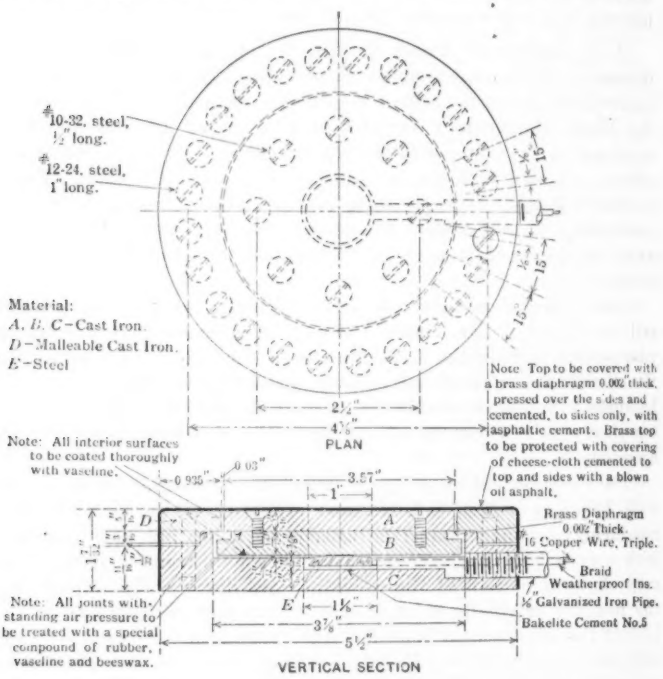
The measurement of pressures transmitted through granular materials has always been difficult, due primarily to the fact that the measuring instrument must be capable of indicating such pressures with only an infinitesimal movement of the instrument itself. The very slightest motion of the weighing face disturbs the soil so that the pressure originally existing may be changed considerably at the instant the measurement is made. Any instrument to be successful for this purpose must be capable of measuring pressures with practically no motion, and the soil-pressure cell mentioned by Mr. Hazen fulfills this requirement.

The principle of its action may best be understood by referring to the cross-section shown in Fig. 16. The underlying idea of this device is to equilibrate the external earth pressure on the weighing face by means of internal air pressure, detecting the instant at which equilibration takes place through the breaking of an electrical circuit within the instrument, and at that instant noting the air pressure required to overbalance the earth pressure.

* Washington, D. C.

Mr. Goldbeck.

Referring to Fig. 16, the soil-pressure cell is seen to consist of a cast-iron base, *C*, 5½ in. in diameter, in the center of which is cemented a steel button, *E*. Bakelite cement is used for this purpose for the double reason that it is an insulator as well as a cement. A thin brass diaphragm, as thin and flexible as a sheet of paper, is stretched across the base, *C*, and is held in place by the malleable cast-iron ring, *D*. This diaphragm is clamped between two cast-iron disks, *A* and *B*, the



DIAPHRAGM CELL FOR DETERMINING SOIL PRESSURE.

FIG. 16.

lower disk, *B*, bearing on the button, *E*. In order to protect the cell from moisture and to prevent the small annular space between Ring *D* and Disk *A* from becoming clogged with soil, the top of the cell is covered with a brass diaphragm like that between Disks *A* and *B*, and the entire instrument is coated with a layer of cheese-cloth cemented with a blown-oil asphalt. Blown-oil is used for this purpose because of its comparative unsusceptibility to temperature change. A galvanized-

iron pipe connects the pressure cell with a small tank of compressed air which is placed in a portable indicating box containing pressure gauges for reading the air pressure within the cell. An insulated electric wire is led through this pipe to the button, *E*, and the pipe itself furnishes the return circuit. A small dry cell and a miniature electric light are the only other electrical equipment required. The indicating box used with this pressure cell is shown in Fig. 17. Proper control valves are also placed in the air line in order to control very delicately the flow of air from the tank into the pressure cell. Mr. Goldbeck.

Let it be supposed that this instrument is to be used for measuring the pressures back of a retaining wall. The cells are first mounted securely against the wall with their weighing face placed toward the earth fill. It is necessary, of course, to mount the cells before the fill is in place. The pipe connections are led up to an accessible position, and if the cells are to remain in place and the readings continued over a long period, it is desirable to use a double pipe connection, as shown in Fig. 18. Should any water collect in the pipes through condensation or leakage, this fact can be determined very readily merely by allowing the air to flow into one side of the pipe line, the other end being open. If water is present, pressure will be indicated in the air line due to the head of water. The mere fact that water is present, however, does not necessarily spoil the readings of the apparatus, for by the use of a double pipe line, the operator can cause the water to mount into one side of the line while he is taking his readings, which are thus not impaired by its presence.

The operation in taking readings is to open the control valve on the pressure tank, thus allowing the air to flow very slowly into the pressure cell. As long as the cast-iron disk, *B*, in Fig. 16 is in contact with the steel button, *E*, this fact will be indicated by the burning of a small electric light in the indicating box. At the instant, however, that the air pressure within the cell slightly exceeds the soil pressure acting on the outside of the cell, an exceedingly small movement of the plate, *B*, takes place, and it is raised out of contact with the steel button, *E*, the electric light is extinguished, and the operator immediately reads the pressure on one of the test gauges in the indicating box. This records the air pressure within the cell, which necessarily equals the earth pressure acting on the cell. At the same instant the operator releases the air pressure within the cell, for at no time should he allow the air pressure to exceed the soil pressure by more than 0.1 lb. per sq. in., since by so doing the accuracy of future readings would be impaired.

The question of the accuracy of this instrument has been raised by Mr. Hazen, and it may be stated that it was several years before means could be devised for proving the accuracy of the results obtained where measurements of pressure of granular materials were made,

MOUNTING OF SOIL PRESSURE INDICATING APPARATUS.

PIPE AND ELECTRICAL CONNECTIONS OF SOIL PRESSURE INDICATING CELL.

FIG. 18.

Mr. Goldbeck.

although it was a comparatively easy matter to prove the accuracy of the instrument when used in liquids or semi-liquids.

The method pursued in checking these results for granular materials consisted in measuring the movement of the disk, *B*, during the

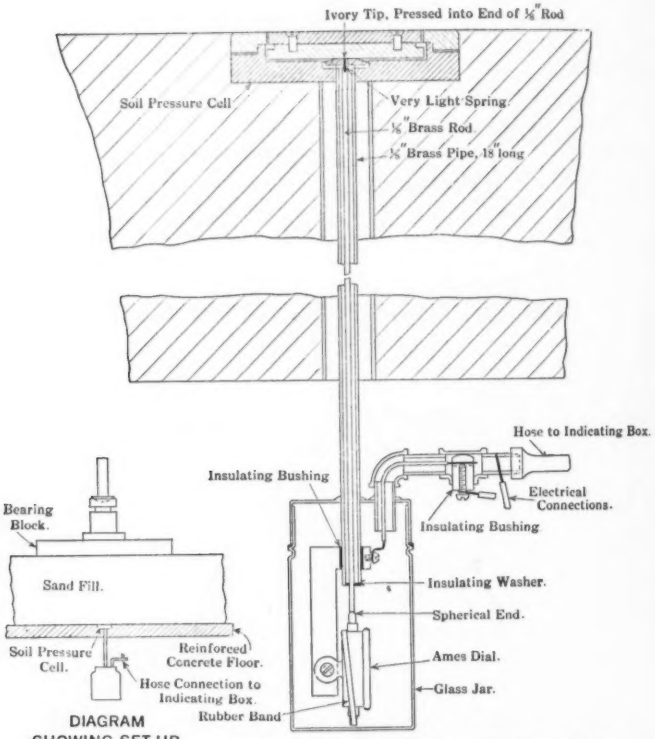

FIG. 19.

breaking of the electrical contact. For this purpose a special set-up of the instrument was used, as shown by Fig. 19. The cell was placed flush with the surface of a reinforced concrete floor and 3 ft. of sand was placed over the cell. In place of the wire ordinarily used in the pipe line leading to the cell, a brass rod having an ivory tip bearing

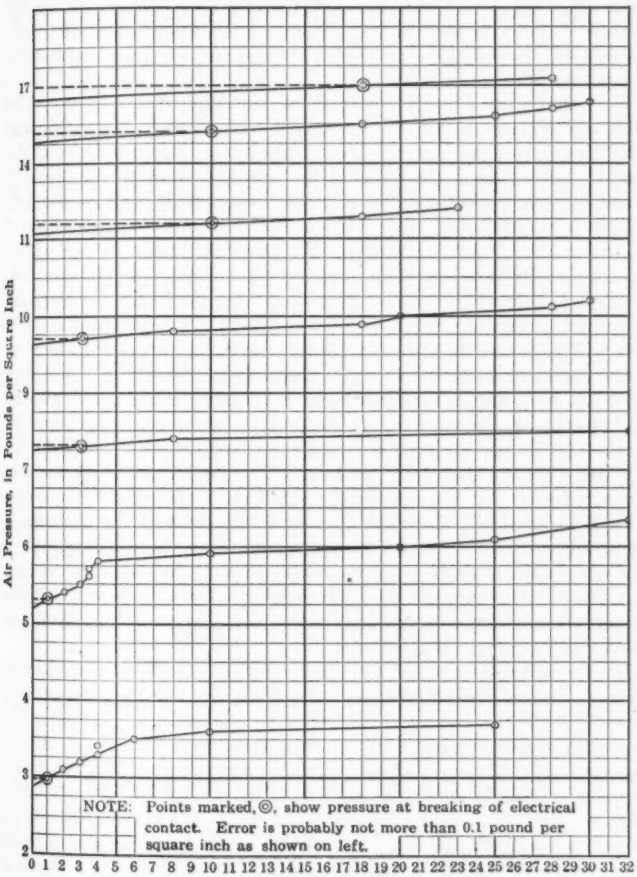

FIG. 20.

Mr. Goldbeck.

on the movable disk of the cell was used. The other end of this rod bore on the plunger of an Ames dial reading movements of 0.0001 in. Concentrated loads were placed on a bearing block resting on the sand fill over the cell and thus definite unit pressures were transmitted to the cell. Air was introduced and simultaneous readings of the air pressure in the cell and movements of the movable diaphragm were recorded at the breaking of the electrical contact, and also after contact was broken.

The curves on Fig. 20 show these simultaneous readings. The double circle shows how much movement took place in the instrument up to the point of breaking the electrical contact, and the circles to the right of the double circle indicate the movements after the breaking of such contact. Before the electrical contact is broken the soil pressure is counterbalanced by the internal air pressure plus whatever pressure exists on the steel button, *E*. After contact is broken within the cell, the air pressure alone counterbalances the soil pressure and, therefore, it is known definitely how much increase in internal pressure is required to produce definite movements of the movable disk.

It will be noted that the movement required to break the electrical contact for external pressures up to about 15 lb. per sq. in. is less than 0.0001 in. and, for low pressures, only 0.00001 in. It will also be noted from the curves that, in general, an increase in pressure of less than 0.1 lb. per sq. in. is required in order to move the disk against the earth pressure 0.0001 in., or less. The small increase in pressure necessary to produce the exceedingly small movement of the diaphragm required to break the electrical contact is the error of the instrument, and this is not more than 0.1 lb. per sq. in., since, in general, a movement of less than 0.0001 in. is required to break the electrical contact. By virtue of the exceedingly small movement required to break the contact, the pressures in granular materials may be accurately determined with this type of instrument.

Numerous applications of this device have been made for measuring pressures transmitted through earth. Thus, the distribution of concentrated loads through sand fills has been determined.* In addition, pressures have been measured back of several retaining walls. At the suggestion of Charles H. Paul, M. Am. Soc. C. E., Assistant Chief Engineer of the Miami Conservancy District, the Bureau of Public Roads conducted an extensive series of tests in an hydraulic fill, in co-operation with the Miami Conservancy District, the test being made in a stand-pipe 41 ft. in height and 30 in. in diameter.† Typical curves resulting from this test correspond very well with those obtained by the Miami Conservancy District in pressure measurements

* "The Distribution of Pressures Through Earth Fills", *Proceedings*, Am. Soc. for Testing Materials, Vol. XVII (1917).

† "Tests to Determine Pressures Due to Hydraulic Fills", *Engineering News-Record*, April 18th, 1918, p. 758.

made with the same apparatus in hydraulic-fill dams.* The Bureau of Public Roads has also made measurements of pressures of concrete against forms with this instrument,† and has utilized it for making measurements of pressure transmitted to the sub-grades of roads.‡ Mr. Goldbeck.

As a result of these tests it was demonstrated that pressure cells of this character may be used successfully for measuring pressures under a variety of circumstances, even in hydraulic fills, for periods up to two years and perhaps longer. The hydraulic-fill pressure measurements demonstrated that material such as is used in the core of an hydraulic-fill dam acts as a perfect fluid during the early stages of settlement, but that it loses its fluid qualities as consolidation proceeds.

As a result of experience with this instrument, the writer believes it to give thoroughly reliable results, not only in liquids and semi-liquids, but even in granular materials such as densely compacted sand. It has also been demonstrated that the instrument is sufficiently rugged to withstand field conditions, and it might very readily be applied in obtaining useful data on many types of construction.

GEORGE L. DILLMAN,§ M. AM. SOC. C. E. (by letter).—This paper is a distinct addition to the literature on earth dams. It is also timely. Mr Dillman.

Before entering upon the discussion, the writer would call Mr. Hazen's attention to one misstatement of fact. Messrs. Schuyler and Howells were not, as he states, pioneers in hydraulic-dam construction. The Chabot or San Leandro Dam was built before they were ever heard of, was largely hydraulicked, was for years the highest earth dam in the world, was never a failure or a partial failure, and suffered no accident during construction.

The analyses of earth dams and slides are identical. Slides have occurred during the construction of many earth dams, due to badly drained core material. The writer refers to the Pilarcitos, Necaxa, and Calaveras Dams. Drainage will avoid such accidents, just as it will cure any slide. The hydraulic-fill type makes a dam of each toe, the pressure coming from the core. When the pressure is too great, failure occurs, not failure of the dam as a whole, but failure of a portion of the toe.

The film of water behind any dam, behind any toe, or behind any slide, has only to be thick enough to be continuous in order to transmit the full pressure of its head under, into, and against the resistant

§ San Francisco, Cal.

Mr. Dillman.

material. It acts like myriads of jack-screws to displace material, and it is often effective, as is proven by the movement of the material.

Drainage may be had in various ways. Mr. Hazen's plan for discarding the fine material is one of them; the coarse material drains itself. Building slowly is another, and building the cores narrow is still another. Building the toes to stand the pressure is effective, but is wasteful of material. The writer would suggest strings of tiles. They are cheaper and fully as effective as any other method; the expense of segregation and discard of fine material suggested by Mr. Hazen is avoided and, on the other hand, excess of material in the toes.

The object in an hydraulic-fill dam (or slide) is to break up the continuity of the film of water, thus killing the head and cause of the trouble. Tile drains are exceedingly cheap, and, properly placed, they will not only stop such accidents, but increase the factor of safety in the completed structure by making the "water-tight surface" or "most nearly water-tight surface", farther up stream than it would be without them.

Safety in a dam is not always reached by tightness. Making it tight in the wrong place is often more dangerous than leaks. In 1916, the writer planned, on a pervious foundation, with pervious material, a dam designed to leak. It does leak, some 160 sec-ft., with 50 ft. of water in the reservoir. There was some active objection, first, because it leaked and, therefore, was dangerous, and afterward, that it was too tight and depleted the ground-water below; both these objections came from the same source, which only goes to show that critics, like the poor, are always with us.

If it is ever desired to decrease the seepage, the writer will advise hydraulicking some fine material over the face of the dam. The dam referred to is the Mackay Dam, on Big Lost River, in Idaho. It is an interesting structure, built strictly in accord with the "great hydraulic principle" announced some 17 or 18 years ago, and some day the writer plans to write a description of it.

He can see no objection to fine material in a dam, if it is placed where it belongs; in fact, he rather favors it.

Mr. Muckleston.

H. B. MUCKLESTON,* M. AM. SOC. C. E. (by letter).—This interesting and timely paper calls attention to certain properties of the colloidal clays which appear to be responsible for the observed phenomena. Sands (which term includes all rock powder, no matter how fine) will settle in water in time, and form a stable sediment. The particles of clay in a colloidal condition or state may remain in suspension for an extraordinary time, measured by years in some cases, and form when they do finally settle, not a stable sediment, but rather

* Lethbridge, Alberta, Canada.

a viscous fluid or jelly which retains water to the extent of 60 to 70% or more of the whole, and will not consolidate further no matter how much time is allowed. Extreme pressure, with the addition of some heat, may convert this mass into shale or slate by expelling the water, but neither of these agencies can be active in the case of hydraulic fills, and, consequently, it is doubtful whether such fills ever do become even reasonably dry. Mr. Muckleston.

The writer has met with this phenomenon on two occasions. On one such occasion a shallow lake formed the most convenient supply of water for camp use. The lake was only about 1 ft. deep, with a blue clay bottom, and the water looked much like good gray paint. Filtering was tried, but without success as no water got through the filter. Sedimentation gave no better results, as the only effect of a week's trial was a thin ring film round the top of the barrel, due to evaporation. A 1-pint sample stood in a glass bottle for more than a year and seemed to be just as turbid as when freshly poured in, although the contents at about 20% of the height of the bottle appeared to be a darker color than the remainder. The water was then allowed to evaporate and left a deposit, apparently about 10% of the original volume, of a light gray powder, much resembling talcum powder, in everything except color, and having no gritty feeling between the teeth.

This clay is the result of hydraulic selection. The lake never has more than about a foot of water and, usually, in four years out of six, none at all except in early spring. It has no outlet. In consequence, the finest particles of soil from the surrounding country have been washed down, and as the water, when there is any, is continually stirred up by wind, the finest particles have been gradually brought to the surface with the colloidal particles on top.

The other occurrence was an attempt to back-fill a retaining wall by hydraulic means. The material available was a sandy clay soil containing small pea-size pebbles, but there must have been an undue proportion of the same kind of clay, because the fill never did consolidate and more than a year afterward was removed by boring holes in the face of the wall and allowing it to flow out. The holes were 1 in. in diameter and the wall 30 in. thick, yet the material poured out much like thick molasses.

This colloidal clay may be thrown down by some of the common mineral salts and in this condition looks like boiled starch with or without some color, and when the water is expelled resembles glue in appearance more than the ordinary conception of clay. It has an extraordinary affinity for water, which it absorbs with great energy, rapidly swelling to its former starchy consistency. If given a less quantity, it is much like pitch—tenacious, sticky, and as hard to handle.

Mr. Muckleston.

The alkalies, such as carbonates of sodium and potassium, act in the reverse way to the acids or neutral salts, resulting in a hard impervious substance which is the base of the soils generally known as hardpan or the like.

Mr. Dunham.

H. F. DUNHAM,* M. AM. SOC. C. E. (by letter).—If it is true that "all earth dams leak", some water must have found its way from the construction pool through the toe on the down-stream side of the Calaveras Dam. No movement or bulging of the earth occurred there to show instability. The factor against such movement has been calculated. Still, it would be of interest to learn what the leakage there amounted to, how general it was, and the elevation at which it occurred or was most noticeable. The two sides were quite similar except that the down-stream side had the more abrupt slope, as the description indicates, but in one respect there was a marked difference. On the down-stream side or toe all leakage was free to escape. On the up-stream toe there was, first, a concrete facing and then the water in the reservoir to hold back any leakage and insure more complete saturation of the material filled in by dump-car or by hydraulic methods.

A cross-section of the dam as it was at the date of the failure showing the height of the concrete facing, the water level in the reservoir, and the known-to-be lowest elevation of very soft or plastic material in the core would be of great interest. Of almost equal value would be a knowledge of the rate of construction of the concrete facing and of the rate of increase in depth of water in the reservoir. Together with these items, the known facts about the quantity or extent of the leakage through the down-stream toe should be recorded, as well as the known leakage on the up-stream side. Without all the data, it would seem to be impossible to make reliable calculations as to stability or devise any factor of safety against sliding movements. So far as the paper shows, the items mentioned were not considered together in their relation to the failure.

As a related feature: If it was noticed at any time during the work that the shore lines of the construction pool were irregular and that the bays extended toward the toes on either side, the elevation of such bays and the distance from the center line of the dam to the shore line should be of interest now, especially if it appeared that the outward bulging on the up-stream slope occurred opposite a bay-head where much fine material had been deposited.

The sliding factor or coefficient of friction may have been assumed for movement along a horizontal plane, but if the up-stream toe had become saturated to the level of the water in the reservoir, while the core and other material above were saturated to an unknown depth,

* New York City.

there would be reason to think that the sliding surface was inclined from the horizontal or toward the base of the outlet tower. How, then, could the real sliding factor be obtained unless that angle of inclination could first be determined? The water in the reservoir would tend to lessen the weight of some of the material in the toe depending, of course, on the extent of the saturation. Mr. Dunham.

Recalling the favorable difference in slope of the two retaining halves or toes of the dam and their great similarity otherwise, there would be some reason to infer that anxiety to complete the concrete facing and to store water led to the Calaveras disaster. If so, there may be a valuable object lesson in the occurrence, in addition to the lessons derived from calculated factors.

Some surprise was caused by the firmness of the core material after the failure. Energy to the extent of many million-foot tons had been expended in that vicinity and in a very short interval of time. A part of that energy may have caused displacement or removal of moisture from the core material. If a large mass of wet concrete falls a considerable distance and stops abruptly, a portion of it will be found to be quite hard and to hold comparatively little water. Had the entire clay core been prepared in some convenient niche in the mountain, several hundred feet above the dam site, and then shot down in 3 or 4 min., the water-tightness would no doubt have been satisfactory. The writer claims no originality for this suggestion. It would be only a feeble imitation of Nature's way in formative processes involving motion and pressure.

WILLIAM H. BURR,* M. AM. SOC. C. E. (by letter).—The hydraulic method for building earth dams has experienced the usual vicissitudes of a comparatively new procedure. The author of this interesting paper has indicated that the method of building an earth dam by hydraulicking the material into place is scarcely more than from 20 to 25 years old. He further observes that the applications of the method have been marked by failures of magnitude, which are due to defective plans of procedure, and not the least prominent among such failures is that of the original Calaveras Dam itself. His paper presents the physical conditions prior to the failure of the dam, which constitute essentially a demonstration of the reasons for the failure. Mr. Burr.

In order that the fine clayey material of the core deposited by sedimentation may constitute a water-tight mass of material, it must, clearly, be divided into minute particles or grains, and apparently it has been assumed in the past that such material cannot be divided too minutely. At first sight this seems to be plausible enough, but the physical analyses of the core material at Calaveras have shown what might be expected, that is, that the finely divided material with

* New York City.

Mr. Burr. an effective size of 0.001 to 0.003 mm., in which the voids may be from 35 to 40% of the total dry volume, has a capillarity of such intensity and affords such great resistance to the flow of water through it, that it is practically impossible to consolidate it by drainage within a reasonable period of time, if at all. It is Mr. Hazen's opinion that no material of an effective size of less than about 0.01 mm. should be used, that being about the smallest grain that will permit suitable drainage, and he is undoubtedly correct in taking that position.

His conclusions are based on extended investigations of the physical character of the material found at Calaveras after the failure, including not only the voids of the core material but the quantity of water held in them, which had not drained out apparently to any material degree, even after lying in the partly completed core volume for more than a year. The experience gained through the failure of this dam and the demonstrative character of the investigations made prove conclusively what has happened in prior and similar failures. The excessively fine material, separated by the hydraulic process and carried into the pond between the two toes of coarse material, refused to give up its water and consolidate. There is little or no reason to suppose that it would drain within a reasonable period of time, even though the supersaturation is as much as 20 per cent. These observations are probably true, irrespective of the character of the core material, provided the effective sizes of the minutely divided particles or grains are no larger than those found at Calaveras. The intense capillarity existing under such circumstances produces a semi-liquid, the intensity of pressure of which may be measured by the head or distance below the free surface.

The possible results attending such a condition of more or less liquidity are generally recognized, but there are some consequences which apparently have not been fully appreciated, even in the Calaveras case. This supersaturated, more or less liquid, mud is practically the same in kind as the vast mud deposits—some subaqueous and others not—which are found in many places. Piles driven into such material are said to carry their loads by "mud flotation". That material never consolidates, nor is there reason to believe confidently that finely divided material in similar condition will drain or consolidate anywhere, even under conditions like those found in an hydraulic-fill dam.

In the Calaveras Dam, therefore, and in other similar hydraulic-fill dams, the core was at least a semi-liquid mass exerting essentially liquid pressure against the coarse material on either side of it, and this observation is not adversely affected by the fact that the demarcation between the coarse and the fine material is not well defined. The author shows all this in a clear and conclusive manner. The large

horizontal forces thus caused to act against the coarse material of the two toes, however, is not all of the influence of this semi-liquid mass in producing displacement and failure of the two toes. The pool was much wider at the bottom than higher up toward the top of the dam. This produced an overhang of coarse consolidated material which in the Calaveras Dam was considerable. The result was a vertical upward pressure against this overhang, varying with the depth below the surface of the pool. This pressure was great enough to be of material effect in aiding the original failure. As it would tend to relieve the pressure on the bottom of the coarse material near the toe, it should be taken into account in considering the coefficient of friction on that bottom. Mr. Burr.

Again, the larger part of the coarse material of the up-stream face was submerged by the water in the reservoir when the failure occurred. All materials so submerged would of course be diminished in apparent weight by the quantity of water displaced. Inasmuch as all the material of the up-stream toe varies in size from gravel to fragments of rock of considerable size, the water would percolate freely through a large amount of the mass, thus relieving the load on the base of the latter. This, also, should be taken into account in the endeavor to find a coefficient of friction, although the manner in which the mass of coarse and fine granular material is pushed along in such violent displacement, induces a condition quite different from that which exists when a heavy continuous body is, in the strict sense of the word, pushed over a continuous surface in the manner of a true slide. In fact, the motion of such a heterogeneous mass of granular material (including even rock fragments) will partake at some points and, perhaps, at a considerable number of points, at least partly, of the nature of confused rolling and sliding, the resistance to which would be much less than that offered by a more or less rigid mass sliding on an irregular rough surface.

Furthermore, the upward pressure of the semi-liquid against the overhang of the coarse material would tend to produce, and, to some extent, undoubtedly would produce, horizontal or inclined openings in that material closely adjacent to the pool and near its bottom, into which some fine material would find its way and act as a lubricant. Whether any quicksand condition would intervene before the motion of the coarse material begins may well be doubted. The rather indefinite material called quicksand does not take on its "quick" character until the water producing supersaturation takes on motion. It scarcely seems to be necessary to imagine that any such condition acted to aid failure prior to the motion of the coarse material of the toes. The lateral and vertical pressure of the supersaturated core material against the up-stream toe, together with the buoyant relief given to

Mr. Burr.

the volume of the coarse material of the up-stream toe due to submergence, is sufficient to account for all that took place.

A review of the literature of this class of engineering work does not disclose a thorough and systematic examination and control of the core material which has hitherto been placed in hydraulic-fill dams. Various rather crude tests of the consistency or degree of consolidation of this material have been made from time to time during the progress of the work, which are well enough as far as they go, but they have fallen seriously short of the necessities of the case by their failure to give quantitative results. No hydraulic-fill dam can be considered as being safely put in place without careful investigations as to the size and supersaturation of the core material at practically all points and at all stages of the work. It is imperatively essential that the character and deposition of that material be completely controlled. A semi-liquid mud will resist a degree of penetration of a heavy object which may be and usually is highly deceptive as a test of consolidation, as pile-driving in such materials constantly demonstrates.

The procedures at Calaveras and San Pablo, after the failure of the former, as set forth by the author constitute probably the first systematic controlling treatment of core material of this kind. The Calaveras failure, therefore, like many other failures, has proven to be of great value to this important field of earth dam construction. It has shown the necessity of determining and limiting the fineness of core material, the amount of its voids, and degree of supersaturation, to the end that its physical characteristics and the process of consolidation may be completely controlled at all stages of the work.

It appears to the writer that with work performed under effective control, it would be desirable to design hydraulic-fill dams with much less volume of core material than has been used heretofore, that is, with a much less width of core. At any rate, material of excessive fineness, as Mr. Hazen indicates, may be profitably wasted.

Mr. O'Shaughnessy.

M. M. O'SHAUGHNESSY,* M. AM. SOC. C. E. (by letter).—This paper presents an interesting résumé of the hydraulic method of constructing dams. The author has added little that is new on this subject beyond that already furnished by J. M. Howells, M. Am. Soc. C. E., and the late James D. Schuyler, M. Am. Soc. C. E., who made successful applications of this process.

The character of the adjacent materials to be incorporated into the structure dominates the type of dam to be constructed in any particular locality. In Southern California, where Mr. Howells has made successful applications of the hydraulic-fill process, the washed detritus is of a gravelly nature which separates mechanically on deposition in

* San Francisco, Cal.

Mr. O'Shaughnessy.

the dam in the manner prescribed by the engineers, the coarser materials going to the extreme up-stream and down-stream portions and the finer materials toward the core. The porosity of the coarse materials permits drainage of the mass, which leaves the structure fairly safe if work is not prosecuted too rapidly.

An intimate knowledge of the geological and mineral characteristics of the neighboring locality, obtained by study and exploration, is a necessary qualification of engineering supervision, in order to build a hydraulic-fill dam which will be safe.

The terrain of Calaveras Valley, where the Calaveras Dam was built, is of a decidedly clayey nature, as indicated by the material deposited in the completed portion of the dam; and the trouble with that structure resulted from the excessive quantity of clay and the fact that the materials deposited by the hydraulic process, on both the up-stream and down-stream slopes, constituted an admirable core material for an earth dam, if the necessary gravel was added, and this very quality prevented the proper drainage of the structure.

When this work was started in 1913, there was no material in the vicinity of Calaveras Valley suitable for hydraulic-fill dam construction. The gravels and sands along the river-bed carried a large content of clay, which was deposited in the foundation portions of the dam, and as the down-stream and up-stream toes are always kept higher than the central pool, they constituted barriers to prevent the drainage of the pool. The original plans for the dam called for a porous material in both the up-stream and down-stream slopes, and it is very clear, therefore, that the material distribution called for by the plans was not followed in the construction of the dam, due to the excess of clayey contents encountered.

No difficulties of this kind have been experienced in the valleys of Southern California, San Fernando, and other places, where the material washed off the mountains is a detritus from crystalline rocks and includes a very small percentage of clay.

The dominant claim of advocates of this type of dam construction is the cheapness of the hydraulic-fill process, but the writer is advised by G. A. M. Elliott, M. Am. Soc. C. E., that, in the case of the Calaveras Dam, this result was not in accordance with predictions. The initial estimate was about 20 cents per cu. yd., while the actual cost was more than 45 cents, and this was in a time of cheap labor. On taking into account the cost of the pipe and the wear on it, the cost of the pumps and their depreciation, and other expenses, it seems to the writer that the steam shovel and good railway equipment would have been much more economical.

It is a wise precaution to put a rock fill both on the up-stream and down-stream toes of all earthen dams. This construction was used by

Mr. O'Shaughnessy.

the writer about 10 years ago on the Throttle Dam, about 70 ft. high, 18 miles southeast of Raton, N. Mex. This dam had a conventional clay puddle core, 20 ft. thick at the bottom and 8 ft. thick at the top, which was built simultaneously with the rolled earth layers about 1 ft. thick, and well watered, on each side of the core. All stone found in the excavation was placed in the down-stream portion of the dam. The puddle core reached a cut-off wall of concrete, carried from bed-rock, at a depth of about 20 ft. into the structure. The down-stream portion of this dam was always kept higher than the up-stream portion, and notwithstanding the fact that floods as great as 8 000 sec-ft. were anticipated and some damage was expected during the construction (of which the owners were advised), this whole work was completed in a satisfactory manner, at a relatively moderate price, and is absolutely tight and safe, with two large spillways cut into the solid rock at each end of the dam.

On behalf of the City and County of San Francisco, which has now under consideration the purchase of the property, the writer has modified the plans prepared by Mr. Hazen, for the completion of the Calaveras Dam, lowering its height to a crest elevation of 775 ft., with the spillway level at an elevation of 753 ft. He has also provided for a rock toe on the up-stream side, and for bringing the construction up in layers, with heavy rolling and watering, in the conventional manner of constructing earthen dams.

The writer disapproved the suggestion of a dam of the Calaveras hydraulic-fill type at the site of the Alpine Dam in Marin County, California, and its adoption by the Directors of the Marin Municipal Water District would inevitably have resulted in a disaster similar to that which took place at Calaveras. A sane, gravity, arched, concrete dam on excellent bed-rock has now been completed at this site and provision made for raising it at a future date, at one-half the ultimate cost of a hydraulic-fill dam.

The true principles controlling dam design and construction have been clearly elucidated by George L. Dillman, M. Am. Soc. C. E., in his discussion* of the Morena Rock Fill Dam. If those principles are adhered to, either for a masonry, earth, or rock fill dam, there will be no danger of any disaster taking place on the completion of the work.

Mr. Morgan.

ARTHUR E. MORGAN,† M. AM. SOC. C. E. (by letter).—So much has yet to be learned about the principles and facts of hydraulic-fill dam construction that every item of added information is pertinent and valuable. Even expressions of opinion with which one cannot agree are of value when they suggest new points of view or methods of inquiry.

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 52.

† Dayton, Ohio.

Mr. Morgan.

Mr. Hazen's opening statement is: "The hydraulic method of dam construction has great advantages, but too many dams built by it have failed." The searches of the engineers of the Miami Conservancy District have developed only two cases of failure of hydraulic-fill dams, namely, the Necaxa Dam and the Calaveras Dam. In case of other failures of so-called hydraulic-fill dams, it was found that this method of construction was not used. In some cases, efforts have been made to construct embankments by sluicing in materials without any attention to their segregation in the dam, and without the proper use of a central pool.

In the case of the Necaxa Dam, conversations with persons employed there have led the writer to the opinion that the cause of this failure was not so difficult to determine as has been indicated by some of the written reports that have appeared, but rather was due to the failure to observe some of the elementary principles of safe construction. Among other conditions which have been described to the writer as contributing to the failure was that of the up-stream toe. He has been informed that an accumulation of muck and unstable material excavated from the site of the dam was allowed to remain within the cross-section on the up-stream side, and that it was at the location of this pile of débris and waste material that the failure occurred. If this information is correct, it would leave the Calaveras Dam as the single instance of the failure of a hydraulic-fill dam built under careful supervision. However, one failure is one too many.

Mr. Hazen's wide experience with sand filters has drawn his attention pointedly to drainage as one of the methods of consolidation of the core of the hydraulic-fill dam. The writer believes, however, that he is mistaken in considering drainage to be the only, or even the most important, factor in consolidation. About fifteen years ago, in the process of reclaiming wet lands, the writer had occasion to drain thirty or forty shallow lakes in Minnesota. These lakes were located in various parts of the State and under widely different soil conditions. Observation there indicated that the fineness of the material which, according to the author, determines the rapidity of drainage and consolidation, did not appear to be the most prominent factor.

In the western part of Minnesota the glacial drift forming the lake beds is composed of powdered limestone and shale in the form of a very fine blue or yellow clay. In some cases, these clay deposits had become so thoroughly compacted under water that a few weeks after the surface water had been drained away, a road roller could be driven over the surface. In the central part of the State some of the lake beds consisted of a mixture of sand, clay, and organic matter. Here, it was frequently possible to push a wooden pole 25 or 30 ft. into the soft mud in the lake bottoms. In the eastern part of the State, the writer has encountered deep deposits of powdered mica of the glacial period,

Mr. Morgan.

which were so unstable as to flow like water. These materials had remained in place through many centuries, and the powdered limestone deposited as erosion from the surrounding hills became almost as firm as hardpan. Between this and other material which retained almost the consistency of a fluid, nearly every degree of consolidation was encountered. The writer is of the impression that the physical and chemical composition of core material and the shape and specific gravity of the particles have much to do with its rate and degree of consolidation.

The consolidation of core material takes place to some extent by the drainage laterally and downward of the enclosed water, as the author suggests, but to a much greater degree by displacement of the water upward, due to vertical pressures and to the settling of the fine material into the voids. The author mentions this upward movement of the water, but his entire argument thereafter seems to repudiate or ignore it.

In the construction of the dams of the Miami Conservancy District, consolidation of the core material actually is taking place at a fairly rapid rate. It is doubtful whether more than a very small part of this consolidation results from drainage, as defined by Mr. Hazen. A clear distinction should be made between the compacting of material by drainage and that by consolidation through settling under water. In the construction of hydraulic-fill dams, engineers are but little concerned with the first method of compacting and very greatly concerned with the second method. As the author's paper is largely taken up with a discussion of methods for insuring drainage by the lateral removal of water, the writer doubts whether it is as applicable to the solidification of the cores of hydraulic-fill dams as to the operation of sand filters.

Recently, at the Lockington Dam of the Miami Conservancy District, the hydraulic fill was interrupted and the surface water drained from the pool. As the surface of the core became dry, there appeared upon it hundreds of small springs discharging water which was being displaced from the core. In each case, a cone was formed of clay carried out with the water. These cones would become about 1 in. high and about 1 ft. in diameter. At another hydraulic-fill dam where work was discontinued until the water in the central pool became clear, these little craters were everywhere evident on the surface of the core under the water, with water pouring out of them like small springs. The confined water evidently forms vertical channels, and through these channels, rather than through the small interstices between the clay particles, the water escapes from the core. The character of these vertical channels can be understood by observing the markings which sometimes appear on the removal of forms from vertical concrete surfaces, especially where an excess of water has been used in mixing the concrete.

That similar vertical channels are formed throughout the mass of newly placed concrete where an excess of water is used, is evident from the appearance on the surface of similar craters from which water pours. Evidently, the size of cement particles does not determine the rate of the ejection of surplus water from the concrete. Mr. Morgan.

Concerning hydraulic-fill dam construction Mr. Hazen states: "It has two fundamental advantages: First, in sorting out the fine particles and placing them in the center of the dam, thus insuring complete water-tightness; and second, in the use of power in place of muscle to the greatest extent." There are other material advantages of this type of construction. Work on a dry, rolled-fill dam commonly is interrupted during rainy weather. Work on a hydraulic-fill dam can continue almost regardless of rain and the condition of the surface. Where rapid progress or haste in making a closure is essential, continuous operation may become an important factor. A water-tight core is highly desirable in a dam, but so also are pervious toes. An ideal hydraulic-fill dam section is one in which the central portion is entirely impervious, whereas the outside portions are so porous that any leakage which may occur, will appear at the base of the dam where it can do no harm, rather than part way up the slope where it may cause a slip.

The author also states: "In general, all the material placed in hydraulic-fill dams may be divided into two classes, namely, toe material and core material." There are three fairly distinct classes of materials in a hydraulic-fill dam: First, the toe material which consists of coarse gravel and sand not readily transported by water; second, the core material consisting of extremely fine particles which remains in suspension, generally for days at a time, falling to the bottom only very slowly; and third, the transition zone between the core material and the toe material, which consists of fine sand, silt, and other material readily moved by water, but which will settle several feet in the course of an hour or so. It is distinctly different from either the core material or the toe material.

Mr. Hazen states concerning core materials: "As a practical proposition, drainage is not possible with such fine materials. By that is meant such prompt and complete drainage as will result in solidification during the construction of the dam." Nevertheless, the writer's experience indicates that consolidation and solidification do take place at a fairly rapid rate. At the Taylorsville Dam, the hydraulic fill was interrupted and a portion of the water drained away. The consolidation was so rapid that whereas at the time of stopping work an iron ball would sink 8 or 10 ft. in the core, within a few months it was possible to walk anywhere over the core, and a horse might even be driven over it. This is true both of that part of the core which was exposed to the air, and of that part which was permanently under water. About 40 or 50% of this core material is finer than the mini-

Mr. Morgan.

mum recommended by the author. A detailed analysis of this core material is presented in the discussion by Charles H. Paul, M. Am. Soc. C. E. When an auger hole was bored into the core, water would rise in the hole and flow out over the surface, being displaced by the weight of the superimposed core material.

Mr. Hazen gives favorable consideration to reducing the thickness of the core until it has almost disappeared, in this way eliminating much of the finest material. If the border line between the core material and the coarser material could be depended on to continue without change during the construction, this method might be feasible, although unnecessarily expensive, as a rule, since it would require the wasting of fine materials. There is no assurance, however, that such uniformity of core margins can be secured. If perfect workmanship and perfect control could be had during construction, one might be assured of an absolutely uniform core margin. As a matter of fact, the margin between coarse and fine material shifts within considerable limits. In the Conservancy District dams, a width of about 25 ft. is maintained on each side of the core where it is assumed that the condition is uncertain. In some cases, a tongue of toe material will shoot out beyond the theoretical lines and tend to make a gravel bar across the dam. In other cases, the flow of water into the pool will result in a bay or depression, leaving the core projecting into the toe material. With the greatest possible care, this fluctuation between toe material and core material can scarcely be held within closer limits than a belt perhaps 15 ft. wide on each side of the pool.

There may be cases where the cross-section of a hydraulic-fill dam might be reduced if lateral pressure of the core material could be eliminated. As a rule, there are other controlling conditions, and a dam properly designed from other points of view will be stable as far as pressure of core materials is concerned. In the Miami Conservancy dams the width of the core is held about equal to the distance down from the top of the dam. As these dams have steeper slopes at the top than at the bottom, the proportion of the width occupied by the core will vary. That the Calaveras Dam had too wide a core there is no doubt, and a definite limit of width of core is essential. In the design of the Conservancy dams, the possibility of failure during construction, due to excess width of core, was a prime consideration.

The experience of the engineers of the Miami Conservancy District leads to the conclusion that there are so many factors entering into the stability of a hydraulic-fill dam that it is not safe to single out any one or two of them and to rely on the theoretical determinations of those factors. The final conclusions are as apt to be empirical as theoretical; or, rather, many problems present themselves for solution, which never would be brought to the attention by theoretical deductions, but only by observation of construction in progress.

Mr. Morgan.

As the construction of the dams of the Miami Conservancy District nears completion, it is the intention of the engineers to make a careful report of their opinions based on this experience. As this construction work is scarcely half completed, it will be a year or more before these opinions and conclusions will be sufficiently definite for presentation.

Mr. Parsons.

H. DEB. PARSONS,* M. AM. SOC. C. E.—The author is to be congratulated on giving such a clear description of a most interesting subject. A rock-fill dam is not exactly in the category of an hydraulic-fill dam, because the material is not washed in by hydraulic streams, although such dams are made tight by the seepage of water through the rock fill itself. The speaker designed a rock-fill dam which was built in 1902, in the Ramapo Hills, near Ramsey, N. J., for the late Mr. George Crocker, of California.

Mr. Crocker desired a dam in order to secure a water supply for his estate, and he had planned a gravity-section stone dam, the plans for which he sent to the speaker for criticism and advice. After an examination of the site, the conclusion was reached that it would be a good opportunity to construct a rock-fill dam. There was rock adjacent to the site, and the earth had a certain quantity of clay mixed with it. The selection of a rock-fill dam was based on the expectation that its construction would be much cheaper and more suitable for the site than the original plan for a cut-stone gravity dam.

This dam is not to be compared, as far as size is concerned, with those which the author has mentioned. Although much smaller, the principles involved are true for dams of larger proportions. The dam was 230 ft. long on the crest, 20 ft. high, and had a top width of 15 ft. It was built with stone roughly dumped in the center, while on the down-stream and on the up-stream faces the stones were placed by hand, in order to obtain some regularity. The slope on the down-stream face was 1 on $1\frac{1}{2}$, and that on the up-stream face 1 on 1, but against the up-stream side an additional earth embankment was placed. The stone was laid roughly. The rocks were brought down from the hillside quarries, and the men simply dumped the core material in place, while carrying up the side faces a little ahead of the center core.

At the up-stream toe there was a cut-off, merely sheet-piling driven into the soil, with some parts ditched and puddled with clay. The pond above the dam covered between 11 and 12 acres. The site was prepared by removing the top surface soil so as to receive the stone which was brought down from both hillsides.

Two 36-in. pipes were built through the dam in order to control the water in the pond, and concrete was used around them to prevent

* New York City.

Mr. Parsons.

leakage of water and to give them strength. They were steel pipes, which, after a time, would rust out, and the concrete was intended to remain and take their place.

The dam had no spillway. It was not expected to be overtopped except at long intervals, and it was designed so that if it was overtopped, a flood would do no harm. The reason for paving the downstream side with large flat stones, especially picked out, was to prevent injury in case the dam should be overflowed.

The dam was finished in six months, having been started in May and finished in November, and its cost was $8 700, so that it is not difficult to figure the saving which this rock-fill construction made

This particular dam leaked during the process of construction, but at the end of six months, when it was finished, it was practically tight. Although it continued to leak, it was substantially tight thirty days after it was finished. Fine material had washed into the interstices of the rock that formed the core and had sealed the voids.

About twenty-five years ago, when the speaker was connected with the Nicaragua Canal Construction Company, the engineers proposed to construct the Ochoa Dam for the purpose of converting the Rio San Juan into a canal. This dam was designed to have an average height of 61 ft. above the river bed, a total length, including concrete abutments, of 1 900 ft., and a width at the base varying from 400 to 1 000 ft. It was proposed to construct the dam by depositing loose rocks and boulders which were expected to become water-tight by the lodgment of clay, sand, and drift. Although the dam received considerable discussion at the time, no question was raised as to its stability. There are locations where a rock-fill dam is more suitable than an hydraulic-fill dam.

Mr. Binckley.

GEORGE SYDNEY BINCKLEY,* M. AM. SOC. C. E.—The speaker is especially interested in Mr. Hazen's description of the Calaveras Dam and the causes which contributed to its disastrous failure. In this connection there are several points of importance to which it would seem pertinent to call attention. In the first place, where heavy material is deposited in the outer slopes of the structure by running water, the material is not only free from lubricant or light fines, but is incomparably better packed than when it is dumped from wagons or cars. This fact, together with the automatic segregation of coarse from fine materials, which should be characteristic of a well built hydraulic-fill bank, is something that should by no means be lost sight of when such a bank is compared with one constructed as a dry rock fill.

As the speaker pointed out in an article† soon after the failure of the lower Otay Dam some years ago, a dry rock fill of unsegregated

* Los Angeles, Cal.

† *Engineering Record*, June 10th, 1916, p. 769.

material is, if overtopped, capable of becoming gorged with water and in this condition its resistance to movement is enormously decreased, the hydrostatic pressure within the mass tending to its disruption, and its effective weight being decreased by the weight of water displaced. This condition as a matter of fact is what caused the destruction of the Lower Otay Dam, as the best of evidence exists to prove that erosion by the overpour had little or nothing to do with it. This example is mentioned for the purpose of emphasizing the difference in the character of slopes constructed by the hydraulic-fill process, and that of the outer slopes of the Calaveras Dam. Mr. Hazen states that during the earlier stages of construction, the pond, and, therefore, the puddle deposited, extended at times over the greater part of the width of the dam. This fact alone would be quite sufficient to account for the failure, for under such conditions a stratum of very plastic clay could exist between a base of coarser material and a superimposed mass through which the clay could not be extruded. If there is no outlet for the extrusion of a fluid or plastic material, it will support very great unit pressures while, at the same time, retaining its fluid or plastic character. Hence, if at any plane in the slopes of the dam there existed any such stratum of plastic clay, cause for surprise would lie, not in the failure, but in the endurance, of the structure. Mr. Binckley.

Mr. Hazen mentions the possibility that under pressure the coefficient of friction might not be the same as under the conditions existing in the tests. It would seem to be quite safe to assume this possibility, for in the case of a material containing a more or less plastic clay in sufficient quantity to fill the voids, the unit resistance of the clay to change of form would be a constant, while the forces acting to produce movement along any given plane within the mass are variable. The conclusion seems inevitable that, under such conditions, the "coefficient of friction" (which in the case of the dam is actually a shear along the plane of greatest unit stress) would be higher where the forces in action are small, and rapidly decrease as such forces became greater in relation to the resistance of the plastic material to flowage or distortion.

The phenomenon of fluidity under motion of a material which is quite solid when it comes to rest, is mentioned by Mr. Hazen as having been observed in material which ran out from the Calaveras Dam. This is exactly the result to be expected if considered in the light of the foregoing remarks on the subject of the coefficient of friction. The same phenomenon was observed in the case of the Necaxa Dam. Great masses of material which flowed like water on a low gradient were found, when the motion ceased, to be solid, well compacted material containing relatively little water. More striking still are the great rock flows that may sometimes be seen in the West, a classic example being that of Turtle Mountain, in British Columbia, where an enormous

Mr. Binckley.

mass of rock slid off the top of the mountain, ran across a valley and well up the opposite slope before it came to rest—as solid a mass of rock and wreckage as if it had been built in place.

That part of the paper dealing with the Necaxa Dam has for the speaker a particular interest through his long association with the late James Dix Schuyler, M. Am. Soc. C. E., who designed this dam, and under whose direction it was built. In this connection, a little inside history relating to the conditions which preceded the accident to this structure may be of interest. Several months before the break in the up-stream slope occurred, Mr. Schuyler was showing the speaker the progress reports and cross-sections of the dam, and commenting on a curious condition which had developed—the rising of the core material at several points in the pond maintained above the core of the dam, to such an extent that islands were formed. This seemed somewhat of a puzzle, but after the speaker had suggested that it was caused by units of the heavy material of the slopes sinking into the core material and displacing it, he agreed that this was probably the explanation.

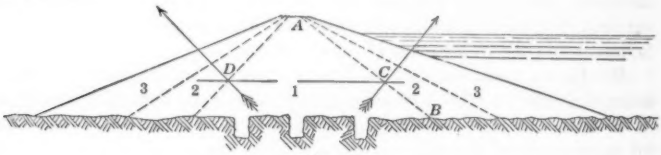

FIG. 21.

At this time, experiments had been made to determine the physical state of the core material, and it had been found that it was possible for two men, working from a boat in the pond, to force a 1½-in. pipe down into the core for a distance of more than 60 ft., demonstrating a condition of semi-fluidity or at least plasticity. This condition suggested to the speaker for the first time a danger that seemed not to have been recognized before, and he immediately called Mr. Schuyler's attention to it. Briefly, it would appear that where the mass of core material (placed in accordance with the designs as practically conventionalized by Mr. Schuyler) is in a semi-fluid or plastic state, it must be regarded as a heavy fluid filling the interior of the dam, and exerting a pressure against the interior of the slopes, not parallel with the base, but upward and normal to a plane corresponding to that zone within the mass at which the character of the material changed from plastic to non-plastic. Fig. 21 will make this clear. Zone 1 is assumed to be semi-fluid or plastic, and Zones 2 and 3 to be a non-plastic material.

It is plain from a consideration of this diagram that as long as the zone of plastic or core material is any wider at the bottom than

Mr. Binckley.

at the top, this condition as regards direction of pressure will exist in corresponding degree. It is also quite plain that the static pressure of the core material considered as a fluid, at Point *D* is dangerously near being in excess of the corresponding weight opposed by the overlying mass of slope material above Point *D*, even if this material is of a much higher specific gravity. Such a condition would threaten the disruption of the dam from internal pressure alone, quite aside from any question of sliding due to horizontal pressure. In the case of the Necaxa Dam, although the speaker believes that Mr. Schuyler was impressed with his suggestion, it was too late to make any change in the design of the dam, as the work was well advanced, and, as a matter of fact, there had been no alarming symptoms. Unfortunately, on account of the scarcity of suitable material, the placing of some very light rock in the up-stream slopes was subsequently permitted. This rock, as the speaker understands it, was practically the same as the well-known "caliche" of Mexico, and was very much lighter than the material previously used. This fact, coupled with the rapid draft of water for power purposes, which lowered the level of the reservoir and removed the support of the water from the upper slope, resulted in what may properly be described as the explosion of the dam. The internal pressure, in amount and direction, was too much for the resistance of the up-stream slope and it went out into the reservoir as did the up-stream slope of the Calaveras Dam.

Shortly after this accident the speaker met Mr. Schuyler in British Columbia, and the former conversation on the subject was recalled. He stated at that time that thereafter he would always limit the impervious core material to a relatively small cross-section, and if he had lived to construct other hydraulic-fill dams, there is not the slightest doubt that he would have corrected the error that he had come to recognize as existing in previous designs; and certainly it is hard to understand how, with the very plain lesson taught by the Necaxa case, the same error could have been committed in the Calaveras Dam, with the aggravating circumstances of slopes of dry fill and of tongues or strata of clay lubricant running out nearly to the slopes, as described by the author.

As regards the Coquitlam Dam, referred to by Mr. Hazen, the material in the core was of a very different character from that commonly found in hydraulic-fill construction. This material was a blue, glacial, so-called clay—actually a very fine silt, having rather remarkable qualities. It is a material with which the speaker became familiar a great many years ago while constructing a dam on the Puyallup River, and is the same as the bulk of material handled in the Seattle re-grade operations. Fine as this material is, and much water as it holds, it has the quality of setting very firmly in a short time. Indeed, its qualities are exactly opposite to those of quick-

Mr. Binckley.

sand, hence neither the speaker nor Mr. Schuyler had any hesitation in using it as a core material for the Coquitlam Dam. This work in collaboration with Mr. Schuyler, was designed and located by the speaker who conducted all the test-pit and tunnel explorations and the stripping of the site, etc. This structure was about 700 ft. long on the crest, was provided with a surface of heavy rip-rap laid in cement mortar both up and down stream, and was protected against overtopping by a spillway 15 ft. deep and, as the speaker remembers it, 250 ft. long through solid rock. For the greater part of its length, the dam rested on the same hard, tight, "glacial clay" already described, abutting on the east end against the diorite ridge in which the spillway was cut. As originally designed, this dam was perfectly safe, and any additions to its section were not improbably made in deference to the same element of the population of that district who opposed the construction of the dam under any conditions. It is possible, however, that a scarcity of suitable material for the heavy slopes developed during construction, in which case, of course, such increase of section as that actually given would have been wise.

In view of the costly lessons of failure and accessible experience in the accepted technique of construction, the desiderata for good design and safe construction of an hydraulic-fill dam would seem to be:

1. Plenty of coarse and heavy material in the slopes, deposited by flowing water, and segregated in such a manner as to form a progressively dense mass from the slopes inward toward the center.

2. The provision of adequate muck trenches or cut-off walls along the zone of the impervious core.

3. The careful avoidance of the introduction of any lubricant in the mass of the slopes.

4. The construction of an impervious core containing enough granular material to destroy or greatly reduce its plasticity, while, at the same time, containing enough clay to secure an impervious or substantially impervious core.

5. The provision of ample spillway capacity to guard against the possibility of the dam being overtopped, and in case of the slightest doubt, to provide a down-stream slope surface capable of carrying, without danger of erosion, a considerable overpour for a few hours.

Mr. Paul.

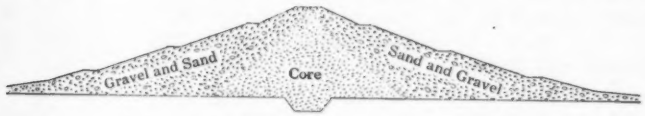
CHARLES H. PAUL,* M. AM. SOC. C. E. (by letter).—The writer is strongly in favor of comparatively narrow cores for hydraulic-fill dams. In several cases which have come to his notice, an unfavorable condition has been introduced by the fact that, in beginning construction, the core width at the bottom was allowed to be so great that the stable material in the outside slopes necessarily overhung portions of the core which had not yet consolidated. This is liable to result in sloughing of

* Dayton, Ohio.

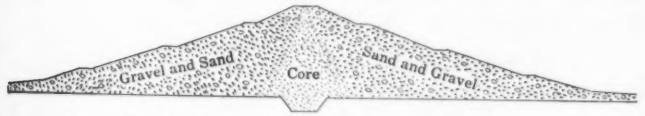
the coarser material into the core, thereby weakening the structure by permitting the core material to encroach still further into the region of the outside slopes. Mr. Paul.

In designing the dams for the Miami Conservancy District, the width of core at any point was limited to the height of the structure above that point. This gave a maximum width of core at the bottom of not more than one-fifth the bottom width of the dam, whereas, in many cases, hydraulic-fill dams have been built with core widths as great as one-third or one-half the bottom width of the dam. Comparison of the wide and narrow core is illustrated in Fig. 22.

One of these sketches, Fig. 22 (*a*), shows a core about one-third the width of the dam at the base, and it may be seen that before construction has progressed very far, the material in the outside slopes will actually overhang the core material. This is an undesirable condition. In the other sketch, Fig. 22 (*b*), the core width at any point is about



Type with Wide Core, Sides Subject to Falling into Core.
(*a*)



Type with Narrow Core, Sides of Superior Stability.
(*b*)

FIG. 22.

equal to the height of the dam above that point. There is very little overhanging of the coarse material, and under such conditions sloughing of the coarser material into the core is practically eliminated.

In a design with the core width at any point equal to the height of the dam above that point, there is no difficulty whatever in obtaining a cross-section stable against sliding and with side slopes as steep as will be permitted by considerations other than the lateral pressure of the core. This point also was carefully worked out in the designs of the Conservancy dams; as a matter of fact, the side slopes of those dams were determined by other considerations.

Fig. 23 is a view of Huffman Dam under construction, showing the comparative width of the core and the volume of stable material in the outside slopes. Dredge pumps located at the toe of the dam (at the stiff-leg derrick) handle the sand and gravel obtained from the

Mr. Paul.

river bottom, pumping it up into the embankment. The hydraulic giant in the foreground is knocking down the clay overburden on the hillside to supply the deficiency of core material. The concrete structure in the distance is a retaining wall forming one side of the outlet structure. The shape of this wall fits the final cross-section of the dam.

There is danger, however, of making the core too narrow, and the writer is inclined to believe that to follow Mr. Hazen's recommendation and make the core "as narrow as possible," or as illustrated in Fig. 3, would not be wise. It is not possible, in construction, to control the width of the core absolutely. Some leeway should be allowed, so that when the coarser material encroaches on the core for reasons beyond the control of the men on the job, there will be no danger of its shooting entirely across the core and resulting in a tongue of coarse material extending all the way through the dam. Also, there is a transition zone between the coarse material and the true core material, which must not be overlooked. The writer is of the opinion that a happy mean, between extremely wide and extremely narrow cores, is the proper thing, and he believes that the design adopted by the Miami Conservancy District is a conservative one from both viewpoints.

As to the gradation of particles in the core itself, several analyses have been made, from time to time, by the U. S. Bureau of Soils, at Washington, D. C., of samples taken from the cores of the five dams now under construction in the Miami Valley. Table 5 gives a typical analysis of the core material from each of these dams.

TABLE 5.—TYPICAL ANALYSES OF CORE SAMPLES.

	Bureau of Soils, standard sizing, in millimeters.	Germantown Dam. Percentage.	Englewood Dam. Percentage.	Lockington Dam. Percentage.	Taylorsville Dam. Percentage.	Huffman Dam. Percentage.
Fine gravel	2 to 1	0	0	0	0	0
Coarse sand	1 " 0.5	0	0.4	0	0	0
Medium sand	0.5 " 0.25	0	0.3	0	0.1	0
Fine sand	0.25 " 0.10	4.2	4.6	1.0	1.9	2.8
Very fine sand	0.10 " 0.05	17.3	19.6	10.1	18.1	15.0
Silt	0.05 " 0.005	56.0	52.7	59.6	59.7	52.5
Clay	0.005 " 0	22.5	22.6	29.3	20.2	29.8

It will be noted that although there is some difference in the gradation, yet, taken as a whole, the samples are after all remarkably similar. This in spite of the fact that each of the dams is in a different river valley, two of them (the Germantown Dam on Twin Creek, and the Lockington Dam on Loramie Creek) being 50 miles apart. A sample of Calaveras core, analyzed by the same methods gave very different results, as it was composed entirely of material finer than 0.05 mm., and 60.1% of it was finer than 0.005 mm. Undoubtedly, a

Fig. 23.—View of Huffman Dam Under Construction.

core of such material would behave quite differently from those represented by the analyses given in Table 5. Mr. Paul.

At the Taylorsville Dam there is an excess of fines in the material available for hydraulic fill, and a considerable percentage of the fines in the core are being wasted. On the other hand, at the Germantown and Huffman Dams, the borrow-pit material is deficient in fines, and additional fines are being sluiced in from the glacial till on the hillsides, to supplement the gravel and sand from the river bottoms. It is a source of satisfaction to the engineers concerned that, in spite of these necessary manipulations of the raw material, it is possible to secure the comparatively uniform results shown in Table 5.

Serious construction difficulties would be encountered at all the Conservancy dams if the limit of fineness of core material was to be held to 0.01 mm., as suggested by Mr. Hazen. Moreover, the cost of construction would be greatly increased, and presumably the imperviousness of the core would be considerably lessened. It should be said, however, that care is being taken not to have a large percentage of the very finest grade, namely, material finer than 0.005 mm. Some of this, it is believed, is quite desirable.

Satisfactory consolidation in the cores of all these dams is taking place, regardless of the fact that about 40 to 50% of the core material is finer than 0.01 mm. This is evidenced by rod tests, ball tests, and pressure-cell readings, as will be shown later.

The writer sees no great advantage in immediate consolidation of the core. Considerable time may be allowed for this process, because of the fact that during construction the height of the dam, and, therefore, the pressure from the partly consolidated core, does not increase greatly from month to month. Provided a reasonable rate of consolidation is assured, the writer feels that there is no need of going to extremes, or sacrificing water-tightness, to secure a more rapid consolidation.

The procedure being followed to secure satisfactory cores in the Conservancy dams and the methods of studying action of the material in the cores have been described in an article entitled, "Study of Pressures in Hydraulic Dam Cores."* This article describes in detail the Goldbeck pressure cells, several of which are in use in the dams of the Miami Conservancy District, for determining pressures in the cores as construction progresses, and particularly for determining the relation between vertical and lateral pressures at various elevations. About three years ago, the writer had occasion to make an investigation of the operation of the Goldbeck pressure cells under various conditions, and outlined with Mr. Goldbeck a series of tests which were conducted by the U. S. Office of Public Roads for the purpose of showing whether or not these pressure cells would give reasonably correct results if

* *Engineering News-Record*, December 25th, 1919.

Mr. Paul.

installed in hydraulic-fill dam cores. Rather elaborate experiments were made, which have been referred to elsewhere.*

The writer is satisfied that this apparatus is the best instrument that has yet been devised for determining the rate of consolidation and for making pressure studies under such conditions. Inasmuch as a full description of this pressure cell has been given by Mr. Goldbeck (page 1764), and also in the *Engineering News-Record* articles previously mentioned, the writer will not take the space here to describe the construction of this cell in detail. Very briefly, it is a closed flat circular box, 5½ in. in diameter (similar to a large shoe-polish box, in shape), the top or bottom of which acts as a movable diaphragm, operated by admitting compressed air, through a small pipe, to the inside of the box. Air is supplied from a small tank which may be charged with an ordinary tire pump. The box being buried in the material to be tested, the movable diaphragm is held down (or in) by the pressure of the material against it. When the pressure of the air admitted to the inside equals that of the material outside, the diaphragm is lifted slightly, an electric contact is broken, and an indicator light in the registering apparatus goes out. The pressure gauge on the air line, at that instant, indicates the pressure of the material against the movable diaphragm. The operation of the cell in taking such readings requires a movement of the diaphragm of less than $\frac{1}{10\,000}$ in. It works so positively that, by proper manipulation of the air feed, the light may be turned on and off any number of times without moving the pointer on the pressure gauge. The cell may be set horizontally, vertically, or at any angle, and thus may record the pressure from any direction. In this manner, valuable comparisons between vertical and lateral pressures may be secured.

There is no comparison between the operation of this pressure cell and the crude foundation tests referred to by the author, and even if they were comparable, the recorded pressures of the Goldbeck cells would be higher than the actual pressures, rather than lower, because of the principles of operation just described. Whether the actual readings are absolutely correct is not vital; the comparative readings are of great interest and value, and, to those who have used the apparatus, give promise of yielding information of considerable importance.

It would be a mistake to attempt to anticipate the conclusions which will finally be drawn from the complete record of pressure-cell tests and other core studies in the Conservancy dams. This subject was investigated very thoroughly before the construction of hydraulic-fill dams in the Miami Valley was undertaken, and extensive studies of the behavior of the core material in these dams have been carried on during the two years or more since construction began. Pressure cells will be installed at all the dams in their maximum sections. This in-

* *Engineering News-Record*, April 18th, 1918, and December 25th, 1919.

stallation at one of the dams has been carried to the extent where interesting results are already available. However, the data will be so much more complete after another year or two that it seems premature to attempt to draw final conclusions from those now at hand. With that limitation, however, the writer feels that the results obtained up to this time are worth presenting. Mr. Paul.

At the Germantown Dam, construction has been carried to a point 60 ft. above river level. This dam will have a maximum height of 110 ft. Pressure cells have been installed in the core at 10-ft. vertical intervals for determining lateral pressures, and at 20-ft. intervals for recording vertical pressures. The results obtained to date are shown in Fig. 24.

There is every indication from these results that the core at the lower elevations is consolidating in a satisfactory manner. The lateral pressures at the lower elevations are considerably less than the vertical pressures, and the diagrams indicate that progressive consolidation is taking place from month to month. At the present time, in the lower portion of the core, the lateral pressures are only about two-thirds of the vertical pressures. At the upper elevations, vertical and lateral pressures are about equal, confirming the generally accepted belief that, at these upper elevations, the core is still a perfect fluid. Viewed as a whole, the readings obtained so far at the Germantown Dam appear to be reasonably correct and suggest no reason for doubting that the pressure cells are giving approximately reliable data. There is also every indication that the core is consolidating rapidly enough for ample safety in construction. Similar data in complete form from all the dams will be available at a later date.

At the Taylorsville Dam, it has been possible to secure actual samples of the core at considerable depth from the surface, after pumping on that section of the dam had been discontinued for the winter. These samples, although they contain perhaps 50% of material finer than 0.01 mm., show without possibility of doubt that the core is solidifying at a satisfactory rate. In fact, at the present time at Taylorsville, it is possible to walk across the core without difficulty, and it has been decided before resuming work on this section of the dam to plow up the core, in order to be sure of obtaining a good bond for the new work.

Penetration tests with the 6-in. cast-iron ball are being made regularly at all the Conservancy dams. Fig. 25 shows the record of ball tests at the Germantown Dam.

The ball sinks to a maximum depth of only about 16 ft., while at the Calaveras Dam the writer is informed that in many cases penetration of the 6-in. cast-iron ball was as great as 50 to 60 ft. Several tests have been made by leaving the ball in place for a period of several days in order to see whether it would gradually continue to settle,

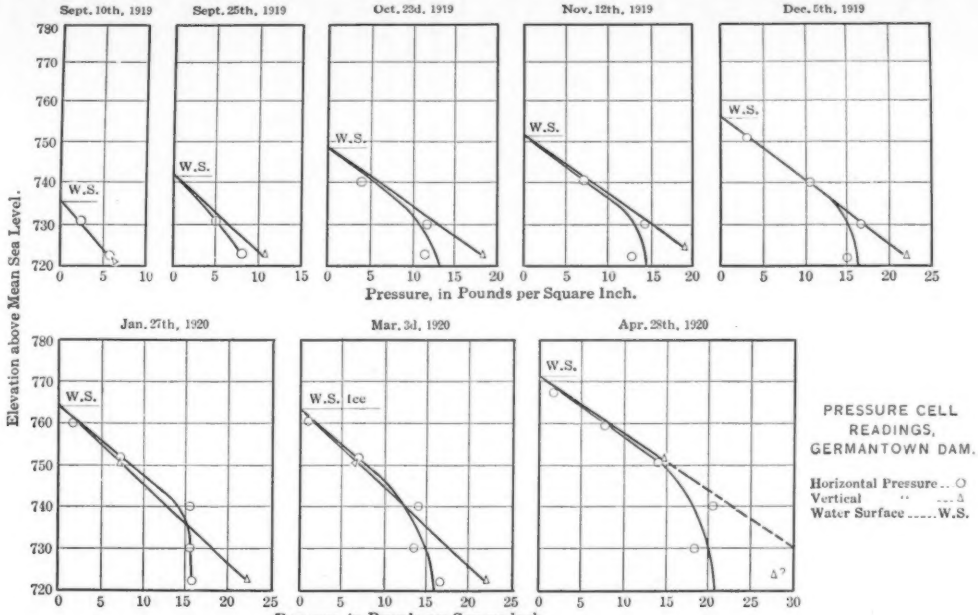


FIG. 24.

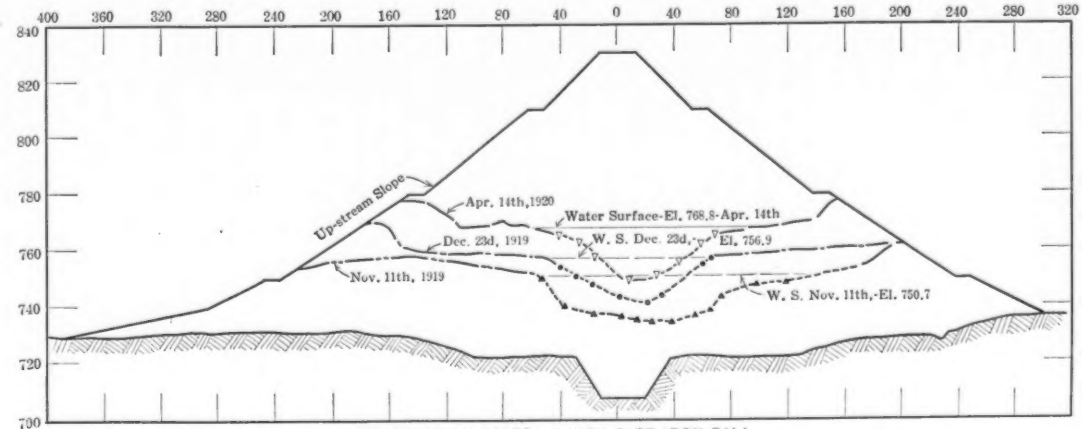
Mr. Paul.



PENETRATION TESTS—6 INCH CAST IRON BALL
GERMANTOWN DAM.

FIG. 25.

Mr. Paul. but it has been found that after the first minute the amount of settlement is generally negligible. It is true that material which will support a 6-in. cast-iron ball is not necessarily very stable, but, on the other hand, it is definitely along the road toward consolidation. It can hardly be called a fluid. Moreover, these ball tests are valuable, owing to the fact that they are being used in other hydraulic-fill dams, and therefore, give means of comparison at dams in various parts of the country. The great difference in ball penetration at Calaveras and at the Conservancy dams, is significant.

Rod tests have also been made at the dams in the Miami Valley, but little value is attached to the results obtained by these methods, as the personal element has such a marked effect on the results. There is nothing very definite about a penetration obtained by two men, working from a boat, with an iron pipe or rod 30 or 40 ft. long. These rod tests, however, do confirm the indications shown by the pressure-cell tests that a satisfactory consolidation of the cores at the lower elevations is taking place. The writer's experience does not confirm the author's statement that material too stiff to be penetrated by the rod will still exert full lateral pressure. This may be disproved by working the rod test in a natural clay bank.

It is interesting to note in this connection, also, that maximum rod penetrations in the Conservancy cores do not exceed about 30 ft., while, at Calaveras, the rod penetrations are reported to have reached depths of from 80 or 90 ft.

The author states that material with 50% voids "is capable of standing up in a boring driven beyond the casing for several feet" and, in another paragraph, that this same material "exerts full lateral pressure, corresponding to its height and weight per cubic foot." The two statements appear to be inconsistent. There is a question in the writer's mind whether the percentage of voids in such material is necessarily a measure of stability. He doubts whether void determinations from boring or other samples are reliable, even as representing the true condition of the core itself, because it is so extremely difficult to bring up a sample in which the moisture content or conditions of compactness has not been disturbed. This is a point which is often disregarded, but which, nevertheless, is very important. The very act of taking a boring sample, especially in such material, tends to compact the sample and change its moisture content.

To one who has not made a study of the history of hydraulic-fill dams, the impression might be gained from Mr. Hazen's paper that many such dams have failed. Such is not the case. Aside from the two failures which have been mentioned, namely, Necaxa and Calaveras, both of which have been fully accounted for, the writer has been unable to learn of any other instances of serious difficulty with

dams built by approved hydraulic methods. On the other hand, there are many such dams in service, throughout the country, at which there has been no suggestion of trouble. In fact, it is apparent that, in a hydraulic-fill dam, construction conditions are generally more severe than those which will be encountered in service; a decided advantage for that type of dam. Mr. Paul.

JOHN E. FIELD,* M. AM. SOC. C. E. (by letter).—The writer was glad to see Mr. Hazen's paper, because heretofore the hydraulic method of construction for earth dams has seemed to be in disrepute, not only with the general public, but among engineers. This disrepute is the result of the failures of the Necaxa and the Calaveras Dams, in particular, and to some other failures not so well known. The failures have naturally attracted more attention than the successes, of which latter there are many. There are in Colorado alone three successes, namely, the Terrace, Santa Maria and Onion Valley Dams, and one failure, the Schaefer Dam, near Florence, Colo. In the case of the Schaefer Dam, the material was entirely unsuitable, being either of yellow clay, or rough angular sand rock, with very little sand or loam. The clay puddle remained the consistency of cream, and when the dam was finally finished by steam shovel and train, the central puddle material was allowed to rise as the dry fill progressed, and finally was drawn off. Mr. Field.

In considering the phenomena of engineering failures, there is generally a difference of opinion, and some mystery; especially is this true of the failure of earth dams. Doubtless, much valuable information and data are suppressed in cases where litigation over damages is in progress. The absence of trained observers before and during the time of failure, and the unreliability of testimony by the casual, but honest, observer, make these differences of opinion possible. In the case of the failure of the Calaveras Dam, the observations are unusually complete and reliable, and its discussion by the Profession should be thorough. This is the excuse for the random comments here presented.

In discussing hydraulic-fill dams, the very different conditions and objects to be attained must be kept in mind. Recently published articles on hydraulic-fill dams have considered particularly the construction period. The troubles at Necaxa and Calaveras were not properly dam failures, and to the general public were of little interest, as they involved neither its life nor property; the owner and the engineer were intensely interested and the latter has given considerable prominence to the phenomena presented. It is better to have one dam in ten fail during construction, than to incur the enormous expense necessary for all in order to insure against the one failure. On the other hand, the failure of one dam when in use involves such great and

* Denver, Colo.

Mr. Field. widespread consequences that any extra precaution and expense is justified to insure the safety of all.

In the failure of earth dams by slipping that have come to the writer's attention, one cause has seemed to predominate, namely, excessive width of core at the base in the ease of hydraulic fills, and poor foundations or permeable base in the case of other dams. The slips at the Wachusetts Dam and at Standley Lake near Denver are examples of the latter.

The writer has read the published accounts of the failure at the Calaveras Dam, and has talked with some engineers who visited the dam before and after such failure. The cause seems to the writer to be quite certain, that is, a layer of fluid material existed under a portion of the upper toe. Whether this layer extended to, and connected with, the puddle core proper is not important. The weight of the dry fill or of the core, or both, transmitted pressure through the layer of fluid material to the lower portion of the upper slope, probably finding the weakest point at or near the upper edge of the concrete paving, for Mr. Hazen has made the following statements:*

"The lower part of the toe had been paved with concrete and this extended 13 ft. above the water level. The top of the concrete formed a conspicuous line and observers say this seemed to rise several feet. * * * * saw the tower 230 ft. high swaying back and forth for a moment, after which it fell in a direction straight away from the dam. * * * * The concrete slope (June 18th, 1917) lifted and cracked parallel to the upper edge and 6 ft. below it for a distance of 700 ft., more or less across the dam."

It appears that a lift of the face near the upper edge of the concrete preceded or was simultaneous with the horizontal movement; whether there was an upward movement of the surface of the fill below the water line is not known, and it may be that the water pressure threw the minimum effective weight of the toe just above the water line, and perhaps also the water caused the puddle on the upper toe in the base of the dam to remain more fluid and to drain less readily than the lower toe which, although lighter in section, did not fail, and the water also saturated and rendered less stable the supporting upper toe. The fact that so many slips in dam enbankments have been on the upper slope, and at a time when water was in the reservoir, leads the writer to suspect that that condition is a contributing cause to failures. The objects of letting water rise on the fill are two: first, to help support the upper toe, and, second, to make use of the water so stored. If the water is drawn off for use, then the first object is lost. In fact, the drawing down of the water may be a menace, as it would leave a more or less saturated upper slope of less stability to support the core pressures.

* *Engineering News-Record*, April 4th, 1919.

This phenomenon is most marked in caving river banks when floods begin to recede. Mr. Field.

It is to be remarked that the failures both at Calaveras and Necaxa were toward the flatter slope, up stream. In the first, there was water in the reservoir, while in the latter there was none at the time of failure, but there had previously been water against the upper face.

It is only natural that in the process of construction the puddle material should extend farther up stream from the center line under the flatter slope than under the steeper lower slope, unless such a result is guarded against. The engineer building any dam, naturally and properly has in mind the safety of the work when in use, rather than its safety during construction. For the completed hydraulic fill, he strives for a well drained lower toe of as great cross-section as is practicable. He also strives for an impervious core of ample thickness, but for the upper toe he desires only a protective coating and support for the puddle core. In ordinary fills the farther up stream the impervious core is, the better. All these considerations tend to place the puddle up stream and under the flatter upper face, and this, if carried too far, would result in failure during construction.

In construction, it seems wise to predetermine the position and minimum thickness of the puddle core and to give the greater stability to the upper toe, especially where water is permitted to rise in the reservoir. The presence of excess width of puddle material in the lower portions of the Calaveras Dam would account not only for the failure, but for the discrepancy in the coefficients of friction as determined by experiment at San Pablo, and as indicated by the failure at Calaveras. The planes of rupture formed by settlements prior to the strengthening of the upper toe were not eliminated by such strengthening, and remained a source of weakness not mentioned by the author.

Mr. Hazen states, referring to hydraulic fills, "experience does not show that the material is graded according to the theoretical section." The coarse materials are deposited near the toes and then filled with finer materials, making a very heavy compact mass with a low percentage of voids. In the experience of the writer, toes so placed were sufficiently impervious during construction to prevent appreciable seepage through them. In practice, also, the sand settles immediately on reaching the water of the pool, and rapidly pushes toward the center, and with each successive raising, and the occasional lowering of the water in the pool, the effect is somewhat as shown in Fig. 26. The points of sand extending into the puddle aid in the drainage.

The minimum thickness of the puddle is the minimum distance between points of sand touching the area, A, of the diagram, and the maximum thickness of the puddle is the maximum width of puddle within areas, A, B, and C. In calculating the weights of toes, the

Mr. Field. minimum thickness of core should be taken, while if the sand and puddle are incorporated by artificial mixing, the thickness of the impervious diaphragm may be taken as the maximum width of the puddle.

In connection with the drainage and saturation in hydraulic and ordinary dams, it may be of interest for the writer to state that at the Terrace Reservoir he had occasion to excavate into the puddle core and also into the portion of the dam placed by teams. The lower 170 ft. of the dam was hydraulicked, while the upper 30 ft. was placed by teams and wagons and thoroughly rolled. In the excavation mentioned, the puddle core was nearly as stiff as material used for making stiff mud brick, and the consistency of the team fill was the same, as far as could be determined by handling and appearance, showing that the team fill had taken on moisture, and the hydraulic fill had lost moisture, until they had each apparently reached a common degree of saturation. Within the line of saturation, one should expect to find similar degrees of saturation in either class of dam.

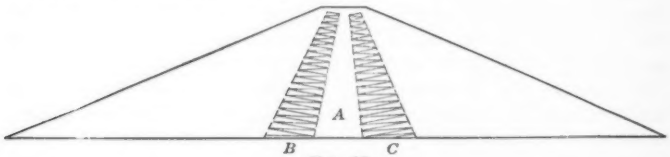


FIG. 26.

At the Terrace Reservoir, the water used in sluicing, particularly during low water in the river, contained a very appreciable quantity of alum in solution, so that it was perceptible to the taste, and its use for domestic purposes was avoided. This fact may have had something to do with the very satisfactory settling of the core material. While fluidity in the puddle increases with depth, increased depth also aids drainage, for under the high pressure present in high dams the water is forced out laterally and the material is consolidated. In the hydraulic fill, the pressure is gradually increased, and the drainage and consolidation are completed in the lowest layers first, the upper layers adjusting themselves as the shrinkage, due to loss of water, progresses. In this matter, the experiments and tests being made by the engineers of the Miami Conservancy District are enlightening.

The author says:

"If drainage and consolidation of the core are not secured, however, safety can only be reached by making each toe large enough to stand the full pressure of the liquid core, and, in that case, in order to be safe, a dam built by the hydraulic method must have flatter slopes and a larger section than is otherwise needed for an earth dam."

This statement is obviously true if one grants the premises for the hydraulic fill, and considers only the dimensions necessary to resist

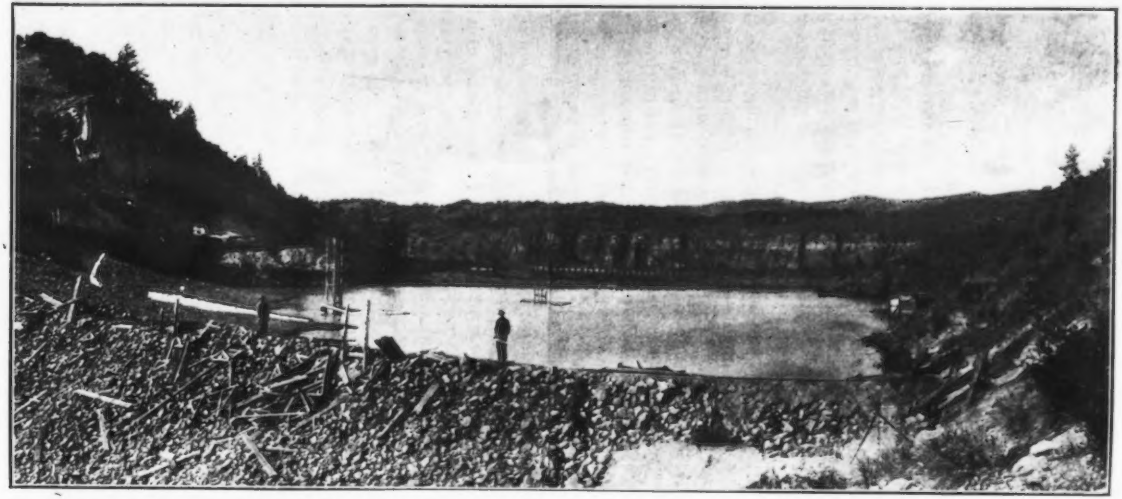

FIG. 27.—TOP OF TERRACE DAM, LOOKING NORTH (UP STREAM), SEPTEMBER, 1910, SHOWING CHARACTER OF TOE MATERIAL, WASTE WELLS AND SETTLING BASIN.

sliding and percolation for the dry fill. In earth-fill dams, however, the slopes, in order to stand, must be at least 1½ to 1, but in order to keep the lower slope outside the line of saturation, it may have to be increased materially, and to have a firm stable bed for the rip-rap facing in the upper slope, it too must be increased. With loose rock rip-rap, a slope of 2½ to 1 is none too flat, and a slope of 2 to 1 for the lower slope is necessary, as 1½ to 1 slopes are not stable under the action of the elements. We may assume, in most cases, that the minimum section of an earth dam is a base five times the height plus the crest width, and it remains only to consider whether such a section would be sufficient for an hydraulic fill. Mr. Field.

The writer wishes to comment on that portion of the paragraph quoted, which reads "If drainage and consolidation of the core are not secured, * * *". It is his opinion, first, that with the material generally found, the core does drain and consolidate, and will be self-supporting, and second, where puddle material is not satisfactory, that drainage and consolidation can be secured. Narrowing the settling basin and wasting the material, as suggested, should be avoided where material is as scarce and difficult to obtain as at the Terrace Dam in Southern Colorado. The scattering of coarse material over the surface of the settling basin would aid in both the drainage and consolidation of the core. The core material should be homogeneous, but need not be uniform in size. The ideal condition would be a mixture giving the greatest weight per unit, the greatest impermeability, and the most stable character. Such a material would be a mixture of coarse and fines, as in concrete aggregate. The writer believes that the presence of large boulders in the core is no detriment; that in time such boulders placed in the core would settle to a point where the core would be quite stable. Mr. Hazen states that "material with 50% of voids in a considerable depth, acts essentially as a liquid." The settling of boulders through and into such material would probably entirely overcome the increasing instability due to depth.

However, in practice there should be added to unstable core material, and thoroughly incorporated therein, boulders, gravel, and sand. The method of adding these coarser materials need not be expensive, and will vary according to the plant, equipment, and local conditions. If the minimum thickness of core is first determined, and then measures are taken to secure stability, there need be no material widening of the base beyond that required for other methods.

The author states that "If a factor of safety of 2 is required, the outside slope must be 4 to 1" [on the basis of a coefficient of friction of 0.5 and equal weight of core and toe material] "but in view of the records of slips in actual dams, it may be well to take a higher factor of safety." With this conclusion the writer cannot agree, for the following reasons:

Mr. Field.

First.—As the coefficient of safety is to apply only to the period of construction, a factor of safety of 2, or even less, may be assumed, as the consequences of failure do not involve the public safety, but a factor of 3 would involve very greatly increased expense. At Necaxa, with slopes of 4 to 1, the volume in the fill would have been doubled for the lower toe, and 33% greater for the upper toe, or the 2 000 000 cu. yd. would have been increased far more than was lost by the slip. The same is true of the Calaveras failure, but even on slopes of 4 to 1 and assuming too wide a puddle at the lower levels, there is no assurance that the failures would not have occurred.

Second.—The lower and lighter toes at both Necaxa and Calaveras did not slip.

Third.—The weight of material in toe and core is not equal, but the two materials as suggested by Mr. Hazen are generally as 5 to 4. Assuming that the toe material has a weight of 120 lb. per cu. ft., and the puddle material 100 lb. per cu. ft., with slopes of $2\frac{1}{2}$ to 1, and a coefficient of friction of 0.5, the factor of safety would be 1.5, which seems to be sufficient for the construction period.

Fourth.—Because defects in execution are revealed in the records of the failures, and may now be avoided.

Fifth.—In the increasing of the factor of safety, Mr. Hazen increases the slopes, but increasing the slopes has a tendency to widen the puddle core and extend it under the slopes, which seems to have been the cause of failure at Calaveras.

The writer accepts generally the principles enunciated by Mr. Hazen, but arrives at somewhat different conclusions, as follows:

1.—To limit the size of material to 0.01 mm., about $_2\,\frac{1}{500}$ in., would not necessitate wasting more material than would naturally be wasted in the process of construction, under ordinary conditions.

2.—The puddle should be at a minimum, especially in the lower portion, and care should be taken to have the toes of full width, particularly at the base of the dam.

3.—The study of borings and the measurement of vertical and horizontal pressures, as on the dams being built by the Miami Conservancy District,* are essential.

4.—An ample factor of safety during construction seems to be 2, as the added volume due to a greater factor of safety would generally be greater than the probable loss should failure occur.

5.—Insure the solidity of toes by the use of rock fill placed hydraulically or otherwise. If placed hydraulically, greater weight will generally result.

6.—It is, in the writer's opinion, unnecessary to provide against quicksand conditions.

* *Engineering-Contracting*, June 16th, 1920.

Mr. Field.

A strict application of the principles laid down would probably not reduce the number of hydraulic dams, since their observance would increase the confidence of the public and the Profession in them, although a few, where clay was practically the only available core material, would not be undertaken. Observance of these principles would not materially increase either the volume or cost, but with proper testing would eliminate present uncertainties, and result in the more extensive use of this most useful and economical method of dam construction.

Mr. Hazen states that a 6% slope was necessary at the San Pablo Dam for sluice flumes with wooden bottoms. At the Terrace Reservoir the flume had a grade of 2.9 ft. per 100, and was lined with 6-in. wood blocks, much rock weighing from 50 to 100 lb. was carried, and some was as heavy as 200 lb. The rock was in part rounded, and in part angular; these flumes gave as good carrying efficiency as those lined with steel on the same grade, and were much more economical.

It is to be hoped that further investigations and experiments will be made to determine whether the suggested minimum size of 0.01 mm. for puddle material cannot be very materially increased or decreased with safety; whether the core material, even though of clay, does not drain laterally and consolidate so as to become self-supporting; and whether it is wise to allow water to rise in the reservoir as the fill progresses.

Mr. Holmes.

J. Albert Holmes,* M. Am. Soc. C. E. (by letter).—In this exceedingly interesting and valuable paper, Mr. Hazen has demonstrated the importance of a narrow central pool in hydraulic-fill dam construction and the influence a narrow pool is likely to have on the grain size of the core material.

As a result of his study, he proposes as a minimum for core material an effective size of 0.01 mm., and to waste from the pool any particles finer than this size. The writer is greatly interested in both these features and believes in their effectiveness in producing a stable and impervious structure. He has, however, brought about these conditions in a somewhat different manner.

In Table 2, Mr. Hazen has listed two dams, with one of which the writer was connected as Resident Engineer, and with the other as Resident Engineer for the Consulting Engineers.

The Somerset Dam, at Somerset, Vt., is in the region of the northern ice fields, and the material of construction is a boulder clay. The Paddy Creek Dam is one of a group of four dams at Bridgewater, N. C., and is built of the decayed and disintegrated rock of a non-glacial country.

* Decatur, Ill.

Mr. Holmes.

The method of construction was semi-hydraulic, that is, the material was excavated by steam shovel, loaded into dump cars, hauled to the dam site by steam locomotives, dumped from trestles and dikes, and sluiced into a central pool where segregation and sedimentation took place.

At Somerset, the sluicing water was pumped from the reservoir and delivered through pipe lines laid along both dikes, with hose connections at frequent intervals. The previously loosened material in the dikes did not, of course, require the same quantity or velocity of water necessary to excavate hydraulically and transport material to a straight hydraulic-fill dam. The quantity of water used at Somerset was about 1 sec-ft. as against 15 to 20 sec-ft. at San Pablo.

To regulate the height of pool at Somerset, an overflow was provided. During the first stages of the work there was a discharge from the pool, the flow carrying with it an estimated quantity of 100 cu. yd. of fine material per 24 hours. It was sought to retain this material, rather than to get rid of it, and during much of the time there was no overflow from the pool and the fine particles were retained. That this could be safely done was due to the character of the borrow-pit material, the narrow pool and core, and the wide supporting dikes. Before the pool was formed, the outer dikes were built up by dumping, first from the trestles and then over the edge of the dikes.

At Somerset, it was desired to give the core a broad base, covering the middle-third of the dam and making seepage travel long at the junction of the core with the stripped surface. There was no cut-off trench. After forming the broad base the core was narrowed quickly so that at completion it occupied one-fifth the cross-section.

The pool width varied from about 60% of the width at the base of the dam, to less than 30% at the top. Sluicing from the dikes into the pool left all gravel and boulders in the dikes. The size of the rock going into the dam was limited only by the capacity of the shovels to load it.

The dikes were watched carefully for movement during construction, but no movement was detected. They were broad and stable at all stages of the work. A complete mechanical analysis was not made of the Somerset core, but individual samples showed 94% passing a 200-mesh sieve, the maximum size being about 0.10 mm.

The core of this dam would probably be placed by Mr. Hazen in the 0.001 to 0.002-mm. effective size class. The dam has been in use nearly seven years and is perhaps entitled to be listed with "A Number of Earth Dams That Have Stood Successfully."

The material of which the Bridgewater Dams were built contained very little that could be classified as clay, and the deeper the excavation was carried in the borrow-pits, the coarser the material became.

Mr. Holmes.

The problem here was to get enough fine material to form the cores. On the other hand, the disintegrated rock did not furnish sound and durable gravel and boulders to give weight and permeability to the outer dikes, although the resulting structures were in every way satisfactory.

The Somerset method of dumping from trestles and dikes was followed at Bridgewater. The sluicing was done from scows floated in the pools on which were mounted monitors and pumps, taking the water from the pools and using it over and over. No overflows were provided; the seepage and evaporation losses amounted to about 0.4 sec-ft. and were made up by pumping from the reservoir to the pool. By this method of sluicing, that is, with water being taken from and returned to the pools and without overflows, all the fine material was retained.

Seepage experiments were made with two combined samples, made up of a large number of smaller samples taken from all parts of the core of two of the dams. These experiments gave a seepage rate for one dam of 30 000 gal. per 24 hours and about 14 000 gal. per 24 hours for the other. This is considering only the core of the dam, from which the samples experimented on were taken.

Mechanical analysis was made of the cores of the three larger dams at Bridgewater. The analysis shows very similar material in the cores of all three dams and that the effective size is nearly three times that suggested by Mr. Hazen as a minimum.

TABLE 6.—EFFECTIVE SIZE AND UNIFORMITY COEFFICIENT OF CORE MATERIALS.

	Catawba.	Linville.	Paddy Creek.
Size at 60% by weight, in millimeters	0.146	0.150	0.157
÷ Effective size (at 10% by weight), in millimeters	0.026	0.028	0.030
= Uniformity coefficient	5.6	5.4	5.2

The Bridgewater Dams have rock in the down-stream toe; at Somerset there is some rock in both toes. The Somerset method of dumping from trestles and dikes and sluicing the fine material from the dikes to the core, insures stable dikes and ready control of pool width and character of core material, and in the writer's opinion, permits the use of a fine core material.

Mr. Swanitz.

H. W. SWANITZ,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper on hydraulic-fill dams sets forth in detail certain principles and theories to be followed in constructing earth-fill dams by the hydraulic process. The author treats the problem as essentially one of filtration and cites

* Vallejo, Cal.

Mr. Swanitz.

an elaborate series of tests and experiments involving microscopic work to determine the size of the grains in the central impervious core, as well as certain tests to arrive at the coefficient of friction of the material.

The paper is based primarily on tests made as a result of the failure of the Calaveras Dam of the Spring Valley Water Company, in California. The assumption is made that practically the same laws of capillarity and drainage apply to the very fine-grained clays as to the fine-grained sands. This may or may not be so, but it has been well known for several years among certain members of the Profession who have had to deal with earth dams, that fine-grained clay drains very slowly and that any embankment (as the core-wall of a dam) deposited under water, will remain in a supersaturated condition for a long time, and, moreover, that this material exerts pressure comparable to pure hydraulic pressure due to a fluid of increased density, the density being that of the core mass.

In the construction of any dam, the type of structure, as well as the method to be used in its construction, is usually indicated quite clearly by the following: (1) the materials at or near the dam site; (2) the importance of the function of the dam (that is, whether it is to form storage for domestic water supply, or power development, or flood protection, etc.); and (3) the amount of money which may justifiably be spent in building the dam. With these facts in mind, if an earth dam is the correct type, then the method of constructing it should receive careful attention. From the list of failures of earth dams, and the well known fact regarding hydraulic pressure just mentioned, it would seem that in the case of any important dam of considerable height, which is to be built in a locality where the available material is mostly pure clay, or rocks largely of a clayey nature, the hydraulic method of construction is definitely indicated.
